CASE REPORT

ENDOSCOPIC TREATMENT OF A BILE DUCT STONE CONTAINING A SURGICAL STAPLE

(Received 18 March 1990)

We report a case of a pigmented gallstone which formed around a surgical staple in the bile duct. The stone was removed and retrieved endoscopically. A brief review of bile duct foreign bodies and gallstones is presented.

KEY WORDS: Choledocholithiasis, foreign bodies, endoscopic therapy

CASE REPORT

A 48 year old female with a history of biliary colic underwent uneventful cholecystectomy in 1979 for gallstones. She was well until November 1988 when she presented with several days of nausea, vomiting and abdominal pain. A HIDA Scan indicated complete obstruction of the common bile duct (CBD). Liver function tests (LFT’s) were consistent with obstruction and the amylase was significantly elevated. The symptoms subsided spontaneously with conservative management and repeat HIDA scan was normal. The presumptive diagnosis was biliary pancreatitis with spontaneous passage of a stone.

One year later she presented with nausea, excruciating abdominal pain, fever and mild jaundice. Again, HIDA scan showed complete obstruction of the CBD, LFT’s were obstructive but the amylase was normal. She had a leukocytosis and blood cultures grew sensitive coliform bacteria. She was treated with ampicillin with a good response. Three days later she was referred to Duke University Medical Center for further evaluation and treatment.

On admission she appeared well with mild biochemical cholestasis. Endoscopy revealed a normal stomach, pylorus, duodenum and ampulla. On fluoroscopy surgical staples were seen in the biliary area. Cannulation of the papilla and cholangiography revealed a dilated bile duct (14mm) with a 14mm filling defect containing a surgical clip (Figure 1). A standard sphincterotomy was performed.
and the stone was grasped with a retrieval basket (Figure 2). The surgical staple moved with the stone, and upon extraction was seen embedded in it. (Figure 3).

Stone analysis revealed calcium bilirubinate (66%) as the major component with cholesterol (30%), mixed bile pigments (3%) and calcium salts of fatty acids (1%) consistent with a primary pigment stone.

The patient did well and was discharged. At four weeks follow up the patient had no complaints.

DISCUSSION

Choledocholithiasis after cholecystectomy is a well known phenomenon. Primary pigment stone formation is usually noted years after surgery and is associated with bile stasis and bacterial action of bilirubin forming a glycocalyx for further deposition of stone substrates. Several different foreign bodies have been implicated as providing a nidus for stone formation in the bile duct. Non-absorbable sutures are most commonly seen, but shrapnel, buckshot, wire fragments, prosthetic tubes, vegetable residue, fishbones, and surgical clips, have also been reported.

Our patient had a history of both pancreatitis and acute cholangitis due to a common duct calculus that formed around a surgical staple. We speculate that the staple eroded through the cystic duct stump and floated into the common duct, providing a nidus for nucleation and stone growth; impaction of the stone caused the episodes of pancreatitis and cholangitis.

Endoscopic sphincterotomy and extraction of calculi is a well accepted, non-surgical alternative treatment for choledocholithiasis. Foreign body extraction has also been reported. However, this is only the second report of endoscopic extraction of a staple-stone combination.
