Screening for β-thalassemia trait (BTT) relies on measuring hemoglobin (Hb) A₂. Since multiple factors can affect HbA₂ levels, the screening can become unreliable. In 1356 healthy Arabs enrolled into a federally funded premarital BTT screening program, the effects of iron deficiency (ID), α⁺-thalassemia trait, gender, smoking, and tribalism on HbA₂ were studied. The complete blood count and hemoglobin fractions were determined on the entire cohort; serum ferritin (<15 μg/L) in 391 subjects was used to determine ID. BTT was present in 29 (2.1%) subjects (HbA₂ >3.5%). Among 77 (20.3%) subjects with ID, the mean HbA₂ (2.30±0.23%) was 0.2% lower than in subjects without iron deficiency (2.50±0.24%, P<0.0001). In 65 (38%)/172 subjects with phenotypic α⁺-thalassemia trait, the mean HbA₂ (2.43±0.24%) was 0.13% lower than in subjects without α⁺-thalassemia trait, P<0.0001. The mean HbA₂ did not differ between males and females, smokers and nonsmokers, and between the tribes. Thus, 35 (2.6%) subjects with HbA₂ between 3.2 and 3.5% were at a risk of false negative diagnosis of BTT. Since iron deficiency and α⁺-thalassemia are both common and both lower HbA₂, modifications in screening recommendations for BTT are proposed.

1. Introduction

Screening for β-thalassemia trait (BTT) depends on measuring hemoglobin (Hb) A₂. Since multiple factors can affect HbA₂ levels, the screening can become unreliable. In 1356 healthy Arabs enrolled into a federally funded premarital BTT screening program, the effects of iron deficiency (ID), α⁺-thalassemia trait, gender, smoking, and tribalism on HbA₂ were studied. The complete blood count and hemoglobin fractions were determined on the entire cohort; serum ferritin (<15 μg/L) in 391 subjects was used to determine ID. BTT was present in 29 (2.1%) subjects (HbA₂ >3.5%). Among 77 (20.3%) subjects with ID, the mean HbA₂ (2.30±0.23%) was 0.2% lower than in subjects without iron deficiency (2.50±0.24%, P<0.0001). In 65 (38%)/172 subjects with phenotypic α⁺-thalassemia trait, the mean HbA₂ (2.43±0.24%) was 0.13% lower than in subjects without α⁺-thalassemia trait, P<0.0001. The mean HbA₂ did not differ between males and females, smokers and nonsmokers, and between the tribes. Thus, 35 (2.6%) subjects with HbA₂ between 3.2 and 3.5% were at a risk of false negative diagnosis of BTT. Since iron deficiency and α⁺-thalassemia are both common and both lower HbA₂, modifications in screening recommendations for BTT are proposed.
The aim of this study was to investigate some of potential factors affecting HbA2 and its implications for BTT screening.

2. Methods

2.1. Setting and Study Population. The subjects \( n = 1356 \) of this study were healthy young UAE adults, who were planning to marry; as mentioned earlier, premarital screening for BTT is mandatory and government funded. Data were collected between 2007 and 2012 in the screening center in the city of Al Ain, Abu Dhabi, UAE. During two six-month long window periods, data on 965 and 391 consecutive subjects, respectively, were collected. The characteristics of some of the study subjects were previously reported [15]. The study was approved by Al Ain Medical District Human Research Ethics Committee, and all participants signed a written consent.

2.2. Laboratory Tests. Complete blood count was performed on blood samples collected in EDTA tubes and was analyzed on the Cell-Dyn Sapphire (Abbott Diagnostics, USA) analyzer. Hemoglobin fractions were measured using high-performance liquid chromatography (Variant II, Biorad Co.) and capillary method (Sebia Co., France); the results of the two methods are comparable [16]. All screening tests were performed in the same laboratory at Al Ain Hospital, Al Ain, Abu Dhabi; the hospital subscribes to the United Kingdom National External Quality Assessment Scheme. All analytes used in the study met internal and external quality standards. Serum ferritin levels were determined in 391 consecutive individuals by an electrochemiluminescence technique using the Roche e411 Cobas immunoassay analyzer (Roche Diagnostics, Mannheim, Germany) in the research laboratory of the College of Medicine and Health Sciences, UAE University, Al Ain, Abu Dhabi, UAE.

2.3. Diagnostic Criteria. DNA gene tests were not performed in the study. BTT was documented when subject had the HbA2 > 3.5%, MCV < 80 fl, and there was no abnormal hemoglobin variant present. Red cell microcytosis was defined as mean corpuscular volume (MCV) <80 fl. Two definitions for iron deficiency were used: (1) ferritin < 15 \( \mu \)g/L (which is more specific) and (2) ferritin < 30 \( \mu \)g/L (which is more sensitive) [17]. \( \alpha \)-thalassemia trait was phenotypically defined when a subject had (1) MCV < 80 fl, (2) HbA2 ≤ 3.5%, (3) ferritin ≥ 30 \( \mu \)g/L, and (4) RDW ≤ 14.0. Subjects with MCV > 80 fl, HbA2 ≤ 3.5%, ferritin ≥ 30 \( \mu \)g/L, and RDW ≤ 14.0 were considered to have a normal genotype. In this population, \( \alpha \)-thalassemia trait is due to \( \alpha^+ \)-deletions and mutations [8, 18]. Kinship groups (tribes) were defined by family names of study subjects and were coded to preserve confidentiality. A trained nurse took the basic clinical history documenting the smoking status, gender, and a family history of thalassemia.

2.4. Statistics. Standard descriptive statistical methods were used. In analysis, cutoff value of >3.5% was used to separate normal from elevated HbA2 levels. Student-\( t \) test was used to compare means of HbA2 in both groups with other variables and between subgroups. Chi-squared test was used for no parametric variables. ANOVA test was used to test the equality of HbA2 means between major tribes. Statistical significance was defined with two-tailed \( P \) value less than or equal 0.05. Data were coded and analyzed with SPSS statistical software version 19.0 (Chicago, IL, USA).

3. Results

3.1. Sex, Age, and Subjects with and without BTT. Of 1356 females, 50.6% were female. The mean age of males (26.0 ± 6.7 years, range 16–69) was three years higher than that of the females (22.9 ± 4.6 years, range 11–44). Among these 1356 consecutive cases, 29 (2.1%) had BTT. The distribution of HBA2 is shown in Figure 1.

3.2. Hemoglobin A2 in Non-BTT. In 1,327 subjects without BTT, the mean HbA2 level was 2.61 ± 0.31%.

3.2.1. Hemoglobin A2 in Iron Deficiency. In all 77/379 (20.3%) iron deficient subjects, defined as ferritin <15 \( \mu \)g/L, the mean HbA2 (2.30 ± 0.23%) was 0.2% lower than in subjects without iron deficiency (2.50 ± 0.24%, \( P = 0.0001 \)). When iron deficiency was defined as ferritin <30 \( \mu \)g/L, iron deficient individuals (138/379) had a mean HbA2 (2.39 ± 0.25%) that was 0.1% lower than in individuals without iron deficiency (2.50 ± 0.24%, \( P = 0.0001 \)). In 75/198 (38%) iron deficient females (ferritin <15 \( \mu \)g/L), the mean HbA2 (2.31 ± 0.23%) was 0.17% lower than in iron sufficient females (2.48 ± 0.25%, \( P = 0.0001 \)). When iron deficiency in females was defined as ferritin <30 \( \mu \)g/L, the mean HbA2 (2.38 ± 0.25%) was 0.1% lower than in noniron deficient females (2.48 ± 0.26%, \( P = 0.01 \)). Only 2 of 190 males had ferritin <15 \( \mu \)g/L.

3.2.2. Hemoglobin A2 in \( \alpha^+ \)-Thalassemia Trait. The phenotypically derived diagnosis of \( \alpha \)-thalassemia trait is more reliable in males because they are rarely iron deficient. In 65 males with phenotypic \( \alpha^+ \)-thalassemia trait, the mean HbA2 (2.44 ± 0.20%) was 0.13% lower than in 107 without...
phenotypically derived $\alpha^+-$thalassemia trait ($2.57 \pm 0.23\%$, $P < 0.0001$).

3.2.3. Hemoglobin $A_2$ in Men and Women. In the entire cohort without BTT, HbA$_2$ levels for females ($2.68 \pm 0.65\%$) were lower than males ($2.83 \pm 0.71\%$, $P < 0.0001$). However, in subjects with ferritin $>30\mu g/L$, the mean HbA$_2$ in females ($2.52 \pm 0.22\%$) was not different from males ($2.57 \pm 0.23\%$, $P = 0.10$) implying that sex does not affect HbA$_2$.

3.2.4. Hemoglobin $A_2$ in Smokers. Males smoked tobacco considerably more often (39%, 68/174) than females (2%, 4/171). The red cell count, mean Hb, and mean HbA$_2$ levels were not different between male smokers and nonsmokers ($P = 0.42-0.76$).

3.2.5. Hemoglobin $A_2$ in Kinship Groups. The mean HbA$_2$ level in subjects without BTT did not differ between 14 tribes comprising 62% of subjects (data not shown).

3.2.6. Hemoglobin $A_2$ in Borderline Range. In iron deficient subjects (ferritin $<15\mu g/L$), two standard deviations of HbA$_2$ value are 0.4%. Thus, if individuals with BTT and HbA$_2$ values between 3.6% and 3.9% are iron deficient, they could have nonthalassemic values of HbA$_2$ that are between 3.2% and 3.5%. They are at risk of false negative diagnosis of BTT (Figure 2). We found that 35 of 1356 subjects (2.6%) have HbA$_2$ in the range of 3.2% and 3.5%, a group in which information about iron status is vital and most critical.

3.3. Hemoglobin $A_2$ in BTT. In 29 subjects with BTT, the mean HbA$_2$ was $5.2 \pm 0.5\%$, with values ranging from 3.9% to 6.2%.

3.3.1. Hemoglobin $A_2$ in BTT and Iron Deficiency. Among 12 informative cases of BTT, five with iron deficiency (ferritin $<15\mu g/L$) had lower mean HbA$_2$ ($5.24 \pm 0.23\%$) than seven without iron deficiency ($5.41 \pm 0.45\%$, $P = 0.45$).

4. Discussion

This study substantiates that HbA$_2$ is lower if iron deficiency or the $\alpha-$thalassemia trait are present; it is unaffected by gender, smoking, or tribal allegiance. However, many important questions remain: How valid are these findings? Can they be extrapolated to subjects with BTT? How should these observations impact screening for BTT?

HbA$_2$ was lower in iron deficient BTT carriers compared to noniron deficient BTT carriers; however, the difference was not statistically significant. This finding can be attributed to the small sample size or heterogeneity of $\beta-$thalassemia mutations. In subjects without BTT, HbA$_2$ was lower in individuals who were more iron depleted (ferritin $<15\mu g/L$) than subjects who were less iron depletes (ferritin $<30\mu g/L$). This suggests a "dose effect" of body iron stores on the level of HbA$_2$. In this study, two standard deviation dispersions of HbA$_2$ value around the mean were 0.4% for all subjects and 0.46% for females with iron deficiency. Therefore, subjects with iron deficiency and HbA$_2$ between 3.2% and 3.5% could theoretically have BTT; that is, a false negative test. Of the screened population, 2.6% were within this range of borderline HbA$_2$ values. As it is unknown how many of them have $\beta-$thalassemia mutation (false negative cases are presumed to be rare), the value of routinely evaluating iron stores during BTT screening cannot be ignored. Studies have shown that iron deficiency lowers (while iron repletion increases) HbA$_2$; thereby, the diagnosis from non-BTT carrier may change to BTT carrier and vice versa (reviewed in 1). Since 38% of females and <1% of males in our population had ferritin $<15\mu g/L$, evaluating routinely iron stores (i.e., serum ferritin) among females alone seems appropriate to facilitate effective screening. In addition, serum ferritin (which is not routinely measured during screening) is often requested if borderline HbA$_2$ is encountered. In our study population, additional reasons warrant evaluation of iron stores during premarital screening. A diagnosis (and subsequent treatment) of iron deficiency in our population would benefit a large number of females and subsequently their infants since most women become pregnant after marriage. Moreover, with the high prevalence of $\alpha^+-$thalassemia trait, iron deficiency in females, and BTT in our population, knowledge about iron stores will help community physicians to differentiate between these disorders, all of which are common causes of microcytosis and anemia in our population [7, 15]. Thus, the additional cost of serum ferritin (added to premarital screening of females) in our population is justified due to the high number of women and their children who would benefit from it.

The high frequency of $\alpha^+-$thalassemia in this population, one of the highest in the world, may also affect the diagnosis of BTT [15, 18]. We confirmed that subjects with $\alpha-$thalassemia trait (phenotypically derived) have lower levels of HbA$_2$, an observation also observed by others [2]. However, whether coinheritance of $\alpha^+-$thlassemia affects HbA$_2$ level in subjects with BTT is less certain. In a Chinese population with BTT, the HbA$_2$ level was unaffected by coinheritance of one $\alpha$-globin gene deletion and two $\alpha$-globin gene deleted in cis ($\alpha^\circ$) [1]. In our population, $\alpha-$thalassemia trait is due to two $\alpha$-globin gene deleted in trans ($\alpha^*\alpha^*$) [8, 18]. In patients with
BTT and coinherited α-thalassemia resulting in hemoglobin H disease, HbA2 was found to be normal or elevated [19]. A coinheritance of β-thalassemia and α-thalassemia may result in normal MCV and MCH, a type of silent BTT that could result in a false negative diagnosis of BTT [20]. In our study, only one of 91 subjects with BTT had normal MCV (data not shown). The prevalence of silent β-thalassemia mutations that result in normal level of HbA2 is unknown in our population, and such prevalence is presumed to be low. Our study was not designed to determine the frequency of such mutations. However, in some recent studies, the frequency of silent β-thalassemia mutations (resulting in normal HbA2 level) is reportedly as high as 17% in some populations with endemic BTT [21–23]. Moreover, high prevalence of both iron deficiency (38% in females in our study) and α-gene deletion carriers (49% in other study) in the same population increases the likelihood of their coexistence in BTT carriers [15, 18]. The combined effect of iron deficiency and α-thalassemia on HbA2 in BTT is unknown. Finally, recently it was found that tribalism, resulting in marriages within Kinship groups and heterogeneous distribution of BTT carriers in our population, dramatically increases odds of a BTT carrier marrying another BTT carrier [7]. Therefore, in premartial screening of our population, a combination of several factors increases the uncertainty of a false negative diagnosis of BTT. This justifies a DNA test for β-thalassemia mutation in all individuals with normal HbA2, who plan to marry BTT carriers.

In this study, we also noted that HbA2 levels were not statistically different between men and women without BTT after excluding iron deficient females from the analysis, finding which has been observed earlier [5]. In a study of BTT carriers, the mean value of HbA2 was also not different between males and females after the effect of iron status and type of β-thalassemia mutation were taken into account [1]. In general, there is no good physiological rational for sex-based differences of HbA2. Similarly, smoking in our study did not affect the level of HbA2, a finding which was also observed in one other study [5].

The type of β-thalassemia mutation is a predictor of HbA2 level [3, 4]. In one study, mutation type had a stronger influence on HbA2 level than iron deficiency [1]. Our study population has a high number of different β+ and β0-thalassemia mutations resulting in the heterogeneity of HbA2 levels (Figure 1) [10–13]. While normal HbA2 value did not differ between the tribes, our sample was small for this analysis in BTT carriers.

4.2. Conclusions. In this Arab population, the cumulative risk of all the factors that lower HbA2 (iron deficiency, α-thalassemia, and many uninvestigated β-thalassemia mutations) is higher than appreciated. Since both iron deficiency and α-thalassemia trait are common and both lower the level of HbA2, this decrease in HbA2 may cause some BTT carriers to be missed on screening. As iron deficiency is mostly confined to females, routinely measuring serum ferritin in women is justified. In addition, since marriage between two BTT carriers can be disastrous for the progeny, a DNA test for β-thalassemia mutation is warranted in all subjects without BTT who plan to marry BTT carriers. The benefit of this approach to BTT screening needs to be validated by larger studies.
