Monte Carlo simulations were used to study photon production in a panoramic X-ray tube with a conical tungsten target to determine the optimal characteristics of the target shape and electron beam configuration. Several simulations were performed for accelerating potentials equal to 250 kV, 300 kV, and 500 kV with electron beams of various radii and anode sizes. The angular distribution of the photon intensity was analysed by numerical calculations for an assembly composed of an X-ray tube and an external collimator with a cylindrical hole to simulate a panoramic scanning system with an X-ray pencil beam.

1. Introduction

X-ray techniques are commonly used in the nondestructive testing [1] of industrial parts, material characterisation, security, many medical applications [2–4], and the examination of various other types of specimens [5, 6]. The most common techniques used for obtaining images are radioscopy for 2D imaging and computed tomography for 3D imaging. Additionally, scanning systems based on a pencil-beam technique [1], where an X-ray tube uses either an inclined massive target or a conical target for panoramic scanning, are also commonly used. X-ray tubes with a conical target [7, 8] have the simplest design for 360° panoramic scanning systems [9] and can be used, for example, to inspect oil wells and pipes. For scanning technology, maximising the output X-ray intensity in the collimated beam is important. Variations in the electron beam diameter, the shape of the conical target, and the inclination angle of the output collimated X-ray beam can significantly affect the output X-ray intensity in the collimated beam and limit the performance of the scanning system. However, the literature shows a lack of detailed information published about the effect of the geometrical parameters of an electron beam and a conical target on the intensity of the angular distribution of collimated X-rays in

the 250–500 kV range of accelerating potentials (which is interesting for industrial applications in which the panoramic scanning technique is used). The general purpose of this study was to investigate, using Monte Carlo simulations, the X-ray generation process in an X-ray tube with a conical tungsten anode and cylindrical symmetry. We determined the following parameters for use in practical applications: the intensity of generated X-rays in the energy range of 250–500 keV, the optimal target shape, the angular distribution of the intensity of the generated X-rays, the intensity of collimated photons through a cylindrical hole from an external collimator, and the efficiency of X-ray generation.

2. Description of the Monte Carlo Simulations

Monte Carlo (MC) simulations were performed using the software suite Xenos by Field Precision [10]. The specific program used to generate the Monte Carlo simulations is called GamBet that uses conformal meshes for 2D/3D Monte Carlo simulations of radiation transport in matter [10]. The unitized code suite handles the full range of electron, photon, and positron interactions with high accuracy. Applications include X-ray targets, electron-beam heating, radiographic

FIGURE 1: A geometrical model of the conical tungsten target and electron beam that were used for the MC simulations.

imaging, positron physics, radiation therapy research, and shielding design. GamBet combines Field Precision's finite-element codes with the package PENELOPE [11] and claims the maximal simulation error of 15%. PENELOPE is a public program used to perform MC simulations of electron-photon transport in various materials. The solution volume for the object mesh had different ranges for the different sizes of the tungsten conical anode (the volume depends on the apex angle of the conical anode 2γ , Figure 1) and the different radii of the electron beam (r_e) considered. Table 1 provides information about the solution volume for the mesh for each simulation and the main geometrical parameters. The tungsten conical anode was centred at (0.0 mm, 0.0 mm) in the XY plane. MC simulations were performed for the geometries presented in Table 1 and Figure 1, at electron energies of 250 keV, 300 keV, and 500 keV. The number of high-energy electrons was the same for all simulations: $N_e = 4.613 \cdot 10^5$. The height of the cone was different for different radii of the electron beam and apex angles of the cone because the radius of the base of the cone was the same as the radius of the electron beam for all simulations, as shown in Figure 1.

The radial distribution of electrons in an electron beam was modelled as a Gaussian function of the diameter of the electron beam (D_e):

$$f_e(x, y, D_e) = \frac{1}{2\pi \cdot (D_e/4)^2} \cdot \exp\left(-\frac{x^2 + y^2}{2 \cdot (D_e/4)^2}\right). \quad (1)$$

This electron distribution corresponds to a 90% probability of any electrons occurring within an electron beam with a diameter D_e .

3. Results and Discussion

3.1. The Energy Distribution of Generated Photons. X-ray spectra were generated using an MC generator with electron energies equal to 250 keV, 300 keV, and 500 keV. These spectra were created to investigate the effect of the shape of

FIGURE 2: The energy spectra of X-ray photons generated at an electron energy of 250 keV and at different values of the apex angle of the conical anode; $r_e = 2$ mm.

the conical anode (target) and the electron beam size on the efficiency of X-ray generation and on the angular distribution of the flux of generated photons. The energy distributions of all of the generated X-rays (which were emitted in different directions after being generated but with the same energy within an energy bin of 2 keV) obtained when the electron energy was equal to 250 keV and 500 keV are shown in Figures 2 and 3 for conical anodes with different apex angles and for the 4 mm diameter electron beam. The energy threshold was of 14 keV.

	30			[0; 20]	
	60			[0; 10]	
	90			[0; 10]	
	110			[0; 5]	

It was observed that the shape of the X-ray spectrum of all of the generated photons is the same for different electron beam radii. As can be seen from Figures 2 and 3, there are some differences in the intensity of generated X-ray spectra in the range of energies up to approximately 50 keV for the different types of conical anodes, which showed different apex angle values. These differences occurred because the generated photons had a larger attenuation depth for larger values of the apex angle 2γ . This effect may also depend on the angular distribution of the generated photons, but it has a small influence on the total intensity of the generated photons within 1.0–1.2% for all simulations at different electron energies.

3.2. Angular Distribution of the Flux of Generated X-Rays.

The spatial positions of the generated photons (x_i, y_i, z_i) after the MC simulation were distributed on an external rectangular surface (the conical anode was located inside this cubic solution volume), which was determined by programming a mesh for the volume of simulated objects. To investigate the angular distribution of the photons in cylindrical geometry (which is more useful for the panoramic scanning technique), it is necessary to translate the initial spatial positions of the photons on the surface of the external cylinder into a radius R_c (the value of 10 mm was used). This translation can be performed in the following way. First, we form a ray directed from the initial position of a photon on the rectangular surface to a second position on the cylindrical surface using the following linear coordinate transformation:

$$\begin{aligned} x_{2i} &= x_i + x_{di}t_i \\ y_{2i} &= y_i + y_{di}t_i \\ z_{2i} &= z_i + z_{di}t_i, \end{aligned} \quad (2)$$

where the direction vector (x_{di}, y_{di}, z_{di}) is formed by the normalised components of the momentum vector (p_{xi}, p_{yi}, p_{zi}).

Then, we substitute the ray into the parametric equation for a cylinder:

$$x_{2i}^2 + y_{2i}^2 = R_c^2. \quad (3)$$

Next, we solve for t :

$$\begin{aligned} t_i &= \frac{x_i x_{di} + y_i y_{di}}{x_{di}^2 + y_{di}^2} \cdot \left(\sqrt{1 - \frac{(x_{di}^2 + y_{di}^2)(x_i^2 + y_i^2 - R_c^2)}{(x_i x_{di} + y_i y_{di})^2}} - 1 \right). \end{aligned} \quad (4)$$

Lastly, we substitute the value of t back into the equations in formula (1), which give the new coordinates (x_{2i}, y_{2i}, z_{2i}) of the photons on the surface of the external cylinder. A schematic showing the measurement of the photons on the external cylindrical surface is shown in Figure 4. For each direction from the top of the conical anode with an inclination angle α_j relative to the vertical symmetry axis, the area of the cylindrical sector on the cylindrical surface (ΔS_j) was calculated for a constant value of the output angle $\Delta\theta = 4^\circ$, and the number of photons (ΔN_j) was calculated within this area of the cylindrical sector, making it possible to calculate the angular distribution of the flux of the generated photons as follows:

$$\Phi(\alpha_j) = \frac{\Delta N_j(\alpha_j, \Delta\theta)}{\Delta S_j(\alpha_j, \Delta\theta) \Delta t_s}, \quad (5)$$

$$\begin{aligned} \Delta S_j(\alpha_j, \Delta\theta) &= 2\pi \cdot R_c^2 \cdot \left(\cot\left(\alpha_j - \frac{\Delta\theta}{2}\right) - \cot\left(\alpha_j + \frac{\Delta\theta}{2}\right) \right), \end{aligned} \quad (6)$$

where Δt_s is a normalisation time that depends on the number of the electrons in the beam (N_e) and on the electrical

FIGURE 4: A schematic showing the measurement of the angular distribution of the photon flux in the cylindrical coordinate system.

power (W_T) of the electron beam: $\Delta t_s = eN_e U_T / W_T$, where e is the elementary electron charge and U_T is the accelerating potential of the X-ray tube.

The angular distributions of the flux of generated photons calculated from the MC simulations are shown in Figure 5 for an electron energy of 250 keV and $r_e = 2$ mm. The step size of the inclination angle α_j was $\Delta\alpha = 7^\circ$. For all cases, the electrical power of the electron beam was normalised to 1.0 Watts to obtain useful values of the photon flux for comparison with real-world values.

As shown in Figure 5, the angular distribution of the generated photons is different for different radii of the electron beam and shapes of the conical anode. It was also observed that the shape is different for different electron energies. The maximum value of the photon flux at an inclination angle α_{jm} is one of the most important parameters in this case. The relationships between these parameters are shown in Figures 6, 7, and 8 for different electron energies and geometries.

The errors in the inclination angles α_{jm} were estimated with the step size $\Delta\alpha = 7^\circ$ that was used to calculate the area of the cylindrical sector on the external cylindrical surface (ΔS_j , formula (6)). The errors in the maximum values of the photon flux (Φ_{xm} , at an inclination angle α_{jm}) were calculated as probable statistical deviations in the number of photons (ΔN_j) [12] that were passed through the cylindrical sector ΔS_j using the following relation:

$$\Delta\Phi_{xm}(\alpha_{jm}) = \frac{\Phi_{xm}(\alpha_{jm})}{\sqrt{\Delta N_j(\alpha_{jm}, \Delta\theta)}}. \quad (7)$$

The results, presented in Figures 6–8, allow for the selection of the optimal value of the anode apex angle or the inclination angle for the output X-ray flux if one of these parameters is known. As indicated by the simulations, an accelerating potential in the range of 250–500 kV does not significantly affect the maximum flux of generated X-rays at the same

FIGURE 5: The angular distributions of the flux of generated X-ray photons in cylindrical geometry at different values of the apex angle of the anode for an electron energy equal to 250 keV and an electron beam radius equal to 2.0 mm.

electrical power and at the same radial distance from the symmetry axis of the conical anode. The probable variations are located within the range of the estimated numerical errors. The increase in the flux of generated photons at higher accelerating potentials of the X-ray tube may be due to the dependence of the efficiency of photon generation on the electron energy. This efficiency can be estimated for bremsstrahlung radiation using the following empirical relation [13]:

$$\eta_X \approx (8 \pm 2) \cdot 10^{-10} Z E_e, \quad (8)$$

where the electron energy E_e has units of “eV.” As indicated by formula (8), the increase in the electron energy (or accelerating potential) linearly affects the efficiency of photon generation. However, the range of high-energy electrons in the target medium is also dependent on their energy [14]. Thus, the X-ray photons, generated by electrons with a greater energy, will have a greater attenuation distance inside the target, which will have an exponential effect on the output photon flux.

3.3. The Angular Distribution of Photon Intensity in Collimated X-Ray Beam. To simplify the MC simulations, which require a large amount of computation time, the following simple numerical method was used to simulate an external cylindrical collimator with any thickness ΔR . For this task, it is necessary to know the distribution of the generated photons on the first surface of the collimator (with radius R_c) and that on the second surface (with radius $R_c + \Delta R$). These distributions can be calculated using a second translation of the spatial positions of the photons on the surface with radius R_c to the surface with new radius $R_c + \Delta R$; moreover,

FIGURE 6: The dependences of the inclination angle, associated with the maximum value of the flux of generated X-rays (a), and the maximum value of the flux of generated X-rays (b) on the value of the apex angle of the conical anode at different electron beam radii: 0.5 mm (1), 2.0 mm (2), and 5.0 mm (3). The electron energy is 250 keV.

FIGURE 7: The dependences of the inclination angle, associated with the maximum value of the flux of generated X-rays (a), and the maximum value of the flux of generated X-rays (b) on the value of the apex angle of the conical anode at different electron beam radii: 0.5 mm (1), 2.0 mm (2), and 5.0 mm (3). The electron energy is 300 keV.

FIGURE 8: The dependences of the inclination angle, associated with the maximum value of the flux of generated X-rays (upper plot), and the maximum value of the flux of generated X-rays (lower plot) on the value of the apex angle of the conical anode at different electron beam radii: 0.5 mm (1), 2.0 mm (2), and 5.0 mm (3). The electron energy is 500 keV.

it is necessary to estimate the geometrical position of the cylindrical hole inside the collimator. Only photons whose coordinates lie on the hole on the first collimator surface and on the hole on the second collimator surface will be able to pass through the collimator hole. To minimise the statistical deviations in the calculated number of collimated photons, it is possible to simulate the circular slit instead of the hole. This estimate is acceptable because a cylindrical geometry is used, which is symmetrical about the z -axis in any direction. The number of photons will be greater with a circular slit and depend on the radius of the collimator hole (r_c) and on the external radius of the collimator:

$$\frac{\Delta N_{\text{slit}}}{\Delta N_{\text{hole}}} \approx \frac{2\pi (R_c + \Delta R) 2r_c}{\pi r_c^2} = \frac{4(R_c + \Delta R)}{r_c}. \quad (9)$$

A simplified schematic of the measurement of the number of photons that can pass through the collimator slit (or hole) in the model is shown in Figure 9.

The translation of the photon coordinates on the second cylindrical surface was performed by using formulae (2), (3), and (4). As shown in Figure 9, the output X-ray beam (in direct projection through the collimator slit on the conical anode) was offset by a distance $2r_c/\sin(\alpha)$ relative to the position of the top of the cone. The following logical conditions were used to select the photons with a momentum vector directed through the collimator slit. These logical conditions can be used only for Z -coordinates because for each photon located on the cylindrical surface with radius R_c ,

FIGURE 9: A schematic (side view) of the measurement of the number of photons (generated by MC) that can pass through the collimator slit.

the following relation is satisfied: $x_j^2 + y_j^2 = R_c^2$. The condition for the first cylindrical surface is as follows:

$$Z_c + \frac{R_c}{\tan(\alpha)} < Z_{2i} < Z_c + \frac{R_c}{\tan(\alpha)} + \frac{2r_c}{\sin(\alpha)}, \quad (10)$$

where Z_c is the coordinate of the top of the cone and Z_{2i} is the coordinate of the photon with index i after the first coordinate translation onto the first cylindrical surface (from the initial square surface). The condition for the second cylindrical surface is similar:

$$Z_c + \frac{R_c + \Delta R}{\tan(\alpha)} < Z_{3i} < Z_c + \frac{R_c + \Delta R}{\tan(\alpha)} + \frac{2r_c}{\sin(\alpha)}, \quad (11)$$

where Z_{3i} is the Z -coordinate of the photon with index i after the second translation onto the second cylindrical surface with radius $R_c + \Delta R$. The following geometrical parameters of the external collimator were used for all simulations: $R_c = 10$ mm, $\Delta R = 3.5$ mm, and $r_c = 0.45$ mm. Typical results for the simulations of the beam intensity after collimation when the radius of the electron beam is 2.0 mm and the electron energy is 250 keV are shown in Figure 10, with the electrical power of the electron beam normalised to 1.0 Watts.

It was observed that the shape of the function of the angular distribution of the photon intensity after collimation is different for different electron energies, radii of the electron beam, and shapes of the conical anode. The maximum value of the photon intensity in the collimated X-ray beam (at an inclination angle α_{jm}) is one of the important parameters in this case. The relationships between these parameters are shown in Figures 11, 12, and 13 for different electron energies and geometries. A spline interpolation within the obtained statistical errors was used to connect the points on the presented figures. The errors in the inclination angles α_{jm} were estimated to be $2\Delta\alpha = 6^\circ$, and a step $\Delta\alpha$ was used to calculate the number of X-ray photons in the output beam after the collimation (using formulas (10) and (11)). The errors in the maximum values of the photon intensity (I_{xm} , at an inclination angle α_{jm}) were calculated as probable statistical deviations of the number of photons (ΔN_j) that were passed through the collimator using formula (5).

FIGURE 10: The angular distributions of the intensity of collimated X-ray photons (through a collimator hole with radius r_c) in cylindrical geometry at different values of the apex angle of the anode when the electron energy is equal to 250 keV and the electron beam radius is equal to 2.0 mm.

The results, presented in Figures 11–13, allow for the selection of the optimal value of the anode apex angle or the inclination angle that maximises the intensity of the output X-ray beam if one of these parameters is known. The results (except for the precise value of the intensity after the collimation) hold for any collimator with the same ratios between geometrical parameters such as distance from the anode, the collimator thickness, and the diameter of the collimator hole. An accelerating potential in the range of 250–500 kV does not significantly affect the maximum flux of the generated X-rays at the same electrical power and at the same radial distance from the symmetry axis of the conical anode. The difference in the generated flux of X-rays is about 8% that can be explained by the additional attenuation of generated X-rays in target media at electron energy of 500 keV.

3.4. The Efficiency of X-Ray Generation. High-energy electrons have different stopping probabilities for different thicknesses of the tungsten target and therefore have different probabilities of the generation of bremsstrahlung radiation. To determine the efficiency of generated and emitted X-ray photons, several simulations were carried out for electron energies equal to 250 keV, 300 keV, and 500 keV. The X-ray spectra for the accelerating potentials equal to 250 kV and 500 kV are shown in Figures 1 and 2. The efficiency coefficient for the energy transfer from an electron beam to the flux of generated and emitted X-rays for all directions over a solid angle 4π was calculated using the following relation:

$$\eta_X \approx \frac{\sum_j (\partial N_{Xj} / \partial E \cdot \delta E \cdot E_j)}{N_{e0} \cdot E_{e0}}, \quad (12)$$

FIGURE 11: The dependences of the inclination angle, associated with the maximum value of the intensity of collimated X-rays (a), and of the maximum value of the intensity of collimated X-rays (b) on the value of the apex angle of the conical anode at an electron energy equal to 250 keV and electron beam radii equal to 0.5 mm (1), 2.0 mm (2), and 5.0 mm (3).

FIGURE 12: The dependences of the inclination angle, associated with the maximum value of the intensity of collimated X-rays (upper plot), and of the maximum value of the intensity of collimated X-rays (lower plot) on the value of the apex angle of the conical anode at an electron energy equal to 300 keV and electron beam radii equal to 0.5 mm (1), 2.0 mm (2), and 5.0 mm (3).

FIGURE 13: The dependences of the inclination angle, associated with the maximal value of the intensity of collimated X-rays (upper plot), and of the maximal value of the intensity of collimated X-rays (lower plot) on the value of the apex angle of the conical anode at an electron energy equal to 500 keV and electron beam radii equal to 0.5 mm (1), 2.0 mm (2), and 5.0 mm (3).

where $\delta E = 2$ keV is the energy step of the simulated X-ray spectrum, which has energy distribution $\partial N_{Xj}/\partial E$, and N_{e0} is the initial number of high-energy electrons with energy E_{e0} . Formula (12) takes into account only photons unabsorbed in the target. The error in the efficiency coefficient was calculated using the following relation [12]:

$$\delta \eta_X = \frac{1}{N_{e0} E_{e0}} \sqrt{\sum_j \left(\sqrt{\frac{\partial N_{Xj}}{\partial E}} \delta E \cdot E_j \right)^2}. \quad (13)$$

The calculated efficiency coefficients of the energy transfer from the electron beam to the flux of generated and emitted X-rays are shown in Figures 14 and 15 for electron energies equal to 250 keV and 500 keV and for different electron beam radii and apex angles of the conical anode. The theoretical coefficient of total efficiency of X-ray generation was calculated and plotted as well to compare with the efficiency of the output flux of emitted photons. This comparison can help to estimate how the different shapes of the conical anode influence the additional attenuation of the generated photons.

As shown in Figures 14 and 15, an X-ray tube with a conical target shows relatively low X-ray generation efficiency compared to the total efficiency of the generation of bremsstrahlung radiation [13, 15]. The results obtained for different electron energies demonstrate that the additional attenuation inside the target is the main reason for this effect,

FIGURE 14: The dependences of the efficiency coefficients of the energy transfer from the electron beam to the flux of generated and emitted X-ray photons on the apex angle of the conical anode for different electron beam radii and at an electron energy equal to 250 keV.

FIGURE 15: The dependences of the efficiency coefficients of the energy transfer from the electron beam to the flux of generated and emitted X-ray photons on the apex angle of the conical anode for different electron beam radii and at an electron energy equal to 500 keV.

which clearly depends on the range of electron energies in the target medium [14].

4. Conclusions

From Monte Carlo simulations of the X-ray generation process in an X-ray tube with a conical target, several important parameters and dependences were determined: the X-ray

intensity of generated photons in the energy range of 250–500 keV, the optimal target shape, the angular distribution of the intensity of generated X-rays as well as photons collimated through the cylindrical hole of an external collimator, and the efficiency coefficient for energy transfer from an electron beam to a generated X-ray flux. It was demonstrated that the angular distribution of the flux of generated X-rays and the angular distribution of the intensity in a collimated X-ray beam depend on the radius of the electron beam and on the shape of the conical target and that these dependences are different at different accelerating potentials of the X-ray tube. The optimal values of the geometrical parameters of a scanning system based on an X-ray tube integrated with an external collimator were observed to maximise the output X-ray intensity in the beam. These results can be used in practical applications to design scanning systems based on the pencil-beam technique and X-ray tubes with massive conical targets.
