We present a review of vector field models of inflation and, in particular, of the statistical anisotropy and non-Gaussianity predictions of models with SU(2) vector multiplets. Non-Abelian gauge groups introduce a richer amount of predictions compared to the Abelian ones, mostly because of the presence of vector fields self-interactions. Primordial vector fields can violate isotropy leaving their imprint in the comoving curvature fluctuations \( \zeta \) at late times. We provide the analytic expressions of the correlation functions of \( \zeta \) up to fourth order and an analysis of their amplitudes and shapes. The statistical anisotropy signatures expected in these models are important and, potentially, the anisotropic contributions to the bispectrum and the trispectrum can overcome the isotropic parts.

1. Introduction

In the standard cosmological model, at very early times the Universe undergoes a quasi de Sitter exponential expansion driven by a scalar field, the inflaton, with an almost flat potential. The quantum fluctuations of this field are thought to be at the origin of both the Large Scale Structures and the Cosmic Microwave Background (CMB) fluctuations that we are able to observe at the present epoch [1]. CMB measurements indicate that the primordial density fluctuations are of order \( 10^{-5} \) have an almost scale-invariant power spectrum and are fairly consistent with Gaussianity and statistical isotropy [2–6]. All of these features find a convincing explanation within the inflationary paradigm. Nevertheless, deviations from the basic single-(scalar)field slow-roll model of inflation are allowed by the experimental data. On one hand, it is then important to search for observational signatures that can help discriminate among all the possible scenarios; on the other hand, it is important to understand what the theoretical predictions are in this respect for the different models.

Non-Gaussianity and statistical anisotropy are two powerful signatures. A random field is defined “Gaussian” if it is entirely described by its two-point function, higher order connected correlators being equal to zero. Primordial non-Gaussianity [7, 8] is theoretically predicted by inflation: it arises from the interactions of the inflaton with gravity and from self-interactions. However, it is observably too small in the single-field slow-roll scenario [9–11]. Alternatives to the latter have been proposed that predict higher levels of non-Gaussianity such as multifield scenarios [12–18], curvaton models [19–25], and models with noncanonical Lagrangians [26–30]. Many efforts have been directed to the study of higher order (three and four-point) cosmological correlators in these models [11, 22, 29, 31–47] and towards improving the prediction for the two-point function, through quantum loop calculations [10, 48–55]. From WMAP, the bounds on the bispectrum amplitude are given by \( -4 < f_{NL} < 80 \) [56] and by \( -125 < f_{NL}^{\text{eq}} < 435 \) [57] at 95% CL, respectively in the local and in the equilateral configurations. For the trispectrum, WMAP provides \( -5.6 \times 10^5 < g_{NL} < 6.4 \times 10^5 \) [58], \( g_{NL} \) being the “local” trispectrum amplitude from cubic...
contributions (see also [59]), whereas from Large-Scale-Structures data \( 3.5 \times 10^5 < g_{NL} < 8.2 \times 10^5 \) [60], at 95% CL. Planck [61] and future experiments are expected to set further bounds on primordial non-Gaussianity.

Statistical isotropy has always been considered one of the key features of the CMB fluctuations. The appearance of some “anomalies” [62–65] in the observations though, after numerous and careful data analysis, suggests a possible breaking of this symmetry that might have occurred at some point of the Universe history, possibly at very early times. This encouraged a series of attempts to model this event, preferably by incorporating it in theories of inflation. Let us shortly describe the above mentioned “anomalies”. First of all, the large-scale CMB quadrupole appears to be “too low” and the octupole “too planar”; in addition to that, there seems to exist a preferred direction along which quadrupole and octupole are aligned [3, 62, 66–68]. Also, a “cold spot”, that is, a region of suppressed power, has been observed in the southern Galactic sky [63, 69]. Finally, an indication of asymmetry in the large-scale power spectrum and in higher-order correlation functions between the northern and the southern ecliptic hemispheres was found [64, 65, 70–72]. Possible explanations for these anomalies have been suggested such as improper foreground subtraction, WMAP systematics, statistical flukes; the possibilities of topological or cosmological origins for them have been proposed as well. Moreover, considering a power spectrum anisotropy due to the existence of a preferred spatial direction \( \hat{n} \) and parametrized by a function \( g(k) \) as

\[
P(\hat{k}) = P(k) \left( 1 + g(k) (\hat{k} \cdot \hat{n})^2 \right),
\]

the five-year WMAP temperature data have been analyzed in order to find out what the magnitude and orientation of such an anisotropy could be. The magnitude has been found to be \( g = 0.29 \pm 0.031 \) and the orientation aligned nearly along the ecliptic poles [73]. Similar results have been found in [74], where it is pointed out that the origin of such a signal is compatible with beam asymmetries (uncorrected in the maps) which should therefore be investigated before we can find out what the actual limits on the primordial \( g \) are.

Several fairly recent works have taken the direction of analysing the consequences, in terms of dynamics of the Universe and of cosmological fluctuations, of an anisotropic preinflationary or inflationary era. A cosmic no-hair conjecture exists according to which the presence of a cosmological constant at early times is expected to dilute any form of primordial anisotropy [75]. This conjecture has been proven to be true for many (all Bianchi type cosmologies except for the Bianchi type-IX, for which some restrictions are needed to ensure the applicability of the theorem), but not all kinds of metrics and counterexamples exist in the literature [76–78]. Moreover, even in the event isotropization should occur, there is a chance that signatures from anisotropic inflation or from an anisotropic preinflationary era might still be visible today [79–82]. In the same context of searching for models of the early Universe that might produce some anisotropy signatures at late time, new theories have been proposed such as spinor models [83–86], higher p-forms [87–92] and primordial vector field models (see Section 2 for a quick review).

We are going to focus on statistical anisotropy and non-Gaussianity predictions of primordial vector field models. As mentioned above, there are great expectations that Planck and new experiments will, among other things, shed more light on the level of non-Gaussianity of the CMB fluctuations and on the nature of the unexpected anisotropy features we mentioned (see, e.g., [93]). Models that combine both types of predictions could be more easily testable and, from non-Gaussianity measurement, more stringent statistical anisotropy predictions could be produced or vice versa.

Within vector field models, higher order correlators had been computed in [94–98] and, more recently, in [99, 100] for \( U(1) \) vector fields. We considered \( SU(2) \) vector field models in [101, 102]. Non-Abelian theories offer a richer amount of predictions compared to the Abelian case. Indeed, self-interactions provide extra contributions to the bispectrum and trispectrum of curvature fluctuations that are naturally absent in the Abelian case. We verified that these extra contributions can be equally important in a large subset of the parameter space of the theory and, in some cases, can even become the dominant ones.

This paper is structured as follows: in Section 2 we review some vector field models of inflation; in Section 3 we present the \( SU(2) \) model; in Section 4 we provide the results for the two, three and, four-point functions of the curvature fluctuations; in Section 5 we present the non-Gaussianity amplitudes for the bispectrum and for the trispectrum; in Section 6 we show and discuss their shapes; finally in Section 7 we draw our conclusions.

2. Inflation and Primordial Vector Fields

The attempt to explain some of the CMB “anomalous” features as the indication of a break of statistical isotropy is the main reason behind ours and many of the existing inflationary models populated by vector fields, but not the only one. The first one of these models [103] was formulated with the goal of producing inflation by the action of vector fields, without having to invoke the existence of a scalar field. The same motivations inspired the works that followed [104–106]. Lately, models where primordial vector fields can leave an imprint on the CMB have been formulated as an alternative to the basic inflationary scenario, in the search for interesting non-Gaussianity predictions [94–102]. Finally, vector fields models of dark energy have been proposed [107–111]. All this appears to us as a rich bag of motivations for investigating these scenarios.

Before we quickly sketch some of them and list the results so far achieved in this direction, it is important to briefly indicate and explain the main issues and difficulties that these models have been facing. We will also shortly discuss the mechanisms of production of the curvature fluctuations in these models.

Building a model where primordial vector fields can drive inflation and/or produce the observed spectrum of large scale fluctuations requires a more complex Lagrangian than the basic gauge invariant \( \mathcal{L}_{\text{vector}} = - (\sqrt{-g}/4) F^{\mu \nu} F_{\mu \nu} \). In fact, for a
conformally invariant theory as the one described by $L_{\text{vector}}$, vector fields fluctuations are not excited on superhorizon scales. It is then necessary to modify the Lagrangian. For some of the existing models, these modifications have been done to the expense of destabilizing the theory, by “switching on” unphysical degrees of freedom. This was pointed out in [112–114], where a large variety of vector field models was analyzed in which longitudinal polarization modes exist that are endowed with negative squared masses (the “wrong” signs of the masses are imposed for the theory to satisfy the constraints that allow a suitable background evolution). It turns out that, in a range of interest of the theory, these fields acquire negative total energy, that is, behave like “ghosts”, the presence of which is known to be responsible for an unstable vacuum. A related problem for some of these theories is represented by the existence of instabilities affecting the equations of motion of the ghost fields [112–114].

In the remaining part of this section, we are going to present some of these models together with some recent attempts to overcome their limits.

In all of the models we will consider, primordial vector fields fluctuations end up either being entirely responsible for or only partially contributing to the curvature fluctuations at late times. This can happen through different mechanisms. For example, if the vector fields affect the universe expansion during inflation, its contribution $\zeta_A$ to the total $\zeta$ can be derived from combining the definition of the number of e-foldings ($N = \int \frac{H dt}{H_0}$) with the Einstein equation ($H^2 = \frac{8\pi G}{3}(\rho_\phi + \rho_A)$, $\rho_A$ being the energy density of the vector field and $\rho_\phi$ the inflaton energy density) and using the $\delta N$ expansion of the curvature fluctuation in terms of both the inflaton and the vector fields fluctuations (see Section 4). To lowest order we have [96]

$$\zeta_A = \frac{A_i}{2m_p} \delta A_i,$$  \hspace{1cm} (2)

where a single vector field has been taken into account for simplicity ($m_p$ is the reduced Planck mass, $A$ is the background value of the field and $\delta A$ its perturbation). When calculating the amplitude of non-Gaussianity in Section 5, we will refer to this case as “vector inflation” for simplicity.

A different fluctuation production process is the curvaton mechanism which was initially formulated for scalar theories but it is also applicable to vectors [96, 115, 116]. Specifically, inflation is driven by a scalar field, whereas the curvaton field(s) (now played by the vectors), has a very small (compared to the Hubble rate) mass during inflation. Towards the end of the inflationary epoch, the Hubble rate value starts decreasing until it equates the mass vector; when this eventually happens, the curvaton begins to oscillate and it will then dissipate its energy into radiation. The curvaton becomes responsible for a fraction of the total curvature fluctuation that is proportional to a parameter ($r$) related to the ratio between the curvaton energy density and the total energy density of the universe at the epoch of the curvaton decay [96]

$$\zeta_A = \frac{r}{3} \frac{\delta \rho_A}{\rho_A},$$  \hspace{1cm} (3)

where $r \equiv 3\rho_A/(3\rho_A + 4\rho_\phi)$. Anisotropy bounds on the power spectrum favour small values of $r$.

From (2) and (3) we can see that, depending on which one of these two mechanisms of production of the curvature fluctuations is considered, different coefficients will result in the $\delta N$ expansion (see (22)).

In this section, we will describe both models where inflation is intended to be vector field driven and those models in which, instead, the role of the inflaton is played by a scalar field, whereas the energy of the vector gives a subdominant contribution to the total energy density of the universe during the entire inflationary phase.

2.1. Self-Coupled Vector Field Models. A pioneer work on vector field driven inflation was formulated by Ford [103], who considered a single self-coupled field $A_\mu$ with a Lagrangian

$$L_{\text{vector}} = -\frac{1}{4} F_{\mu\nu} F^{\mu\nu} + V(\psi),$$  \hspace{1cm} (4)

where $F_{\mu\nu} = \partial_\mu A_\nu - \partial_\nu A_\mu$ and the potential $V$ is a function of $\psi \equiv B_\mu B^\mu$. Different scenarios of expansion are analyzed by the author for different functions $V$. The universe expands anisotropically at the end of the inflationary era and this anisotropy either survives until late times or is damped out depending on the shape and the location of the minima of the potential.

The study of perturbations in a similar model was proposed by Dimopoulos in [115] where he showed that for a Lagrangian

$$L_{\text{vector}} = -\frac{1}{4} F_{\mu\nu} F^{\mu\nu} + \frac{1}{2} m^2 B_\mu B^\mu, \hspace{1cm} (5)$$

and for $m^2 \approx -2H^2$, the transverse mode of the vector field is governed by the same equation of motion as a light scalar field in a de Sitter stage. A suitable superhorizon power spectrum of fluctuations could therefore arise. In order to prevent production of large scale anisotropy, in this model the vector field plays the role of the curvaton while inflation is driven by a scalar field.

2.2. Vector-Field Coupled to Gravity. The Lagrangian in (5) may be also intended, at least during inflation, as including a nonminimal coupling of the vector field to gravity; indeed the mass term can be rewritten as

$$L_{\text{vector}} \supset \frac{1}{2} (m_0^2 + \xi R) B_\mu B^\mu, \hspace{1cm} (6)$$

where, for the whole duration of the inflationary era, the bare mass $m_0$ is assumed to be much smaller than the Hubble rate and the Ricci scalar $R = -6[\dot{a}/a + (\dot{a}/a)^2]$ can be approximated as $R \approx -12H^2$. For the specific value $\xi = 1/6$, (5) is retrieved.

For the Lagrangian just presented, Golovnev et al. [104] proved that the problem of excessive anisotropy production in the case where inflation is driven by vector fields can be avoided if either a triplet of mutually orthogonal or a large number $N$ of randomly oriented vector fields is considered.
The Lagrangian (6) with $\xi = 1/6$ was also employed in [116], where inflation is scalar field-driven and a primordial vector field affects large-scale curvature fluctuations and, similarly, in [117], which includes a study of the backreaction of the vector field on the dynamics of expansion, by introducing a Bianchi type-I metric.

2.3. Ackerman-Carroll-Wise (ACW) Model. A model was proposed in [118, 119] where Lagrange multipliers ($\lambda$) are employed to determine a fixed norm primordial vector field $B_{\mu}B^\mu = m^2$

$$L_{\text{vector}} = \lambda \left( B^\mu B_\mu - m^2 \right) - \rho_\Lambda,$$  

(7)

where $\rho_\Lambda$ is a vacuum energy. The expansion rate in this scenario is anisotropic: if we orient the $x$-axis of the spatial frame along the direction determined by the vector field, we find two different Hubble rates: along the $x$-direction it is equal to

$$H^x = \frac{\rho_\Lambda}{m^2} \frac{1}{P(\mu)},$$  

(8)

and it is given by $H_0 = (1 + c\phi^2)H_0$ along the orthogonal directions; $\mu \equiv m/m_p$, $P$ is a polynomial function of $\mu$ and $c$ is a parameter appearing in the kinetic part of the Lagrangian that we omitted in (7) (see [118, 119] for its complete expression). As expected, an isotropic expansion is recovered if the vev of the vector field is set to zero.

2.4. Models with Varying Gauge Coupling. Most of the models mentioned so far successfully solve the problem of attaining a slow-roll regime for the vector-fields without imposing too many restrictions on the parameters of the theory and of avoiding excessive production of anisotropy at late times. None of them though escapes those instabilities related to the negative energy of the longitudinal modes (although a study of the instabilities for fixed-norm field models was done in [120] where some stable cases with non-canonical kinetic terms were found). As discussed in [112–114], in the self-coupled model a ghost appears at small (compared to the horizon) wavelengths; in the non-minimally coupled and in the fixed-norm cases instead the instability concerns the region around horizon crossing.

Models with varying gauge coupling can overcome the problem of instabilities and have recently attracted quite some attention. In [94], the authors consider a model of hybrid inflation [121–124] with the introduction of a massless vector field

$$L \ni \frac{1}{2} \left( \partial_\mu \phi \partial^\mu \phi + \partial_\mu \chi \partial^\mu \chi \right) - \frac{1}{4} f^2(\phi) F_{\mu \nu} F^{\mu \nu} + V(\phi, \chi, B_\mu),$$  

(9)

where $\phi$ is the inflaton and $\chi$ is the so-called “waterfall” field. The potential $V$ is chosen in such a way as to preserve gauge invariance; this way the longitudinal mode disappears and instabilities are avoided.

Similarly, Kanno et al. in [125] (see also [96, 126]) consider a vector field Lagrangian of the type

$$L_{\text{vector}} = -\frac{1}{4} f^2(\phi) F^\alpha \rho F_{\alpha \rho},$$  

(10)

but in a basic scalar field-driven inflation model. Very recently, in [127] the linear perturbations in these kind of models have been investigated.

Finally, in [96, 100] varying mass vector field models have been introduced

$$L_{\text{vector}} = -\frac{1}{4} f^2(\phi) F^\alpha \rho F_{\alpha \rho} + \frac{1}{2} m^2 B_\mu B^\mu,$$  

(11)

where $f \sim a^\alpha$ and $m \sim a$ ($a$ is the scale factor and $\alpha$ is a numerical coefficient). The special cases $\alpha = 1$ and $\alpha = -2$ are of special interest. In fact, introducing the fields $A^\mu$ and $A_\mu$, related to one another by $A_\mu = f B_\mu = a A^\mu$ ($A^\mu$ and $A_\mu$ are, resp., the comoving and the physical vectors), it is possible to verify that the physical gauge fields are governed by the same equations of motion as a light scalar field in a de Sitter background. Vector fields in this theory can then generate the observed (almost) scale-invariant primordial power spectrum.

3. SU(2) Vector Model: Equations of Motion for the Background and for Linear Perturbations

Let us consider some models where inflation is driven by a scalar field in the presence of an SU(2) vector multiplet [101, 102]. A fairly general Lagrangian can be the following:

$$S = \int d^4 \sqrt{-g} \left[ \frac{m^2_R}{2} \frac{f^2(\phi)}{4} g^{\mu \nu} g^{\rho \sigma} \sum_{a=1,2,3} F^a_\mu F_a^\mu \right.$$

$$+ \frac{M^2}{2} g^{\mu \nu} \sum_{a=1,2,3} B^a_\mu B^a_\mu + L_\phi \left. \right],$$  

(12)

where $L_\phi$ is the Lagrangian of the scalar field and $F^a_\mu \equiv \partial_\mu B^a_\nu - \partial_\nu B^a_\mu + g_{\mu \nu} f_\rho B^a_\rho$ ($g_\nu$ is the SU(2) gauge coupling). Both $f$ and the effective mass $M$ can be viewed as generic functions of time. The fields $B^a_\mu$ are comoving and related to the physical fields by $A^a_\mu = (B^a_\mu, B^3_\mu/a)$. The free field operators can be Fourier expanded in their creation and annihilation operators

$$\delta A^a_\mu(\vec{k}, \eta) = \int \frac{d^3 q}{(2\pi)^3} e^{i \vec{q} \cdot \vec{x}}$$

$$\times \sum_{\lambda = L, R, \lambda = \text{long}} \left[ e^{i \lambda(\vec{q})} a^{\lambda \dagger}_\nu \delta A^a_\mu(q, \eta) + e^{i \lambda(-\vec{q})} (a^{\lambda \dagger}_a q) \delta A^a_\mu(q, \eta) \right] + \text{c.c.},$$  

(13)

where the polarization index $\lambda$ runs over left ($L$), right ($R$) and longitudinal (long) modes and

$$\left[ a^{\lambda \dagger}_{\vec{k}}(\vec{k}, \eta), a^{\lambda \dagger}_{\vec{k}'}(\vec{k}', \eta) \right] = (2\pi)^3 \delta_{\vec{k},\vec{k}'} \delta(3)(\vec{k} - \vec{k}')\),$$  

(14)
Here, \( \eta \) the conformal time \((d\eta = dt/a(t))\). Once the functional forms of \( f \) and \( M \) have been specified, the equations of motion for the vector bosons can be written. For the most part, the calculations are quite general in this respect. In fact, the expression of all correlation functions, prior to explicating the wavefunction for the gauge bosons, apply to any \( SU(2) \) theory with an action as in (12), both for what we will call the "Abelian" and for the "non-Abelian" contributions. In particular, the structure of the interaction Hamiltonian is independent of the functional dependence of \( f \) and \( M \) and determines the general form of and the anisotropy coefficients appearing in the final "non-Abelian" expressions (see Section 4). When it comes to explicating the wavefunctions, a choice that can help keeping the result as easy to generalize as possible is the following:

\[
\delta B^T = -\frac{\sqrt{\pi}}{2\sqrt{k}} [J_{3/2}(x) + iJ_{-3/2}(x)],
\]

for the transverse mode and

\[
\delta B^l = n(x)\delta B^T,
\]

for the longitudinal mode \((n \text{ is a unknown function of } x \equiv -k\eta)\) [101, 102]. Let us see why. As previously stated, for \( f = a^\alpha \) and with \( \alpha = 0, 1, -2 \), it is possible to verify that the (physical) transverse mode behaves exactly like a light scalar field in a de Sitter background. Considering the solution (15) then takes into account at least these special cases. As to the longitudinal mode, a parametrization was adopted as in (16) in order to keep the analysis more general and given that, because of the instability issues, introducing this degree of freedom into the theory requires special attention. We are going to keep the longitudinal mode "alive" in the calculations we present, by considering a nonzero function \( n(x) \), and focus on the simplest case of \( f = 1 \). This case is known to be affected by quantum instabilities in the longitudinal mode, anyway we choose \( f = 1 \) for the sake of simplicity in our presentation. The results can be easily generalized to gauge invariant models (please refer to [102] for a sample generalization of the calculations to massless \( f = a^{(1,-2)} \) models).

4. Correlation Functions of Curvature Fluctuations: Analytic Expressions

We are now ready to review the computation of the power spectrum, bispectrum, and trispectrum for the curvature fluctuations \( \zeta \) generated during inflation.

\[
\left\langle \zeta_{\mathbf{k}_1} \zeta_{\mathbf{k}_2} \right\rangle = (2\pi)^3 \delta^{(3)}(\mathbf{k}_1 + \mathbf{k}_2) P_{\zeta}(k),
\]

\[
\left\langle \zeta_{\mathbf{k}_1} \zeta_{\mathbf{k}_2} \zeta_{\mathbf{k}_3} \zeta_{\mathbf{k}_4} \right\rangle = (2\pi)^3 \delta^{(3)}(\mathbf{k}_1 + \mathbf{k}_2 + \mathbf{k}_3 + \mathbf{k}_4) \times B_{\zeta}(\mathbf{k}_1, \mathbf{k}_2, \mathbf{k}_3, \mathbf{k}_4),
\]

\[
\left\langle \zeta_{\mathbf{k}_1} \zeta_{\mathbf{k}_2} \zeta_{\mathbf{k}_3} \zeta_{\mathbf{k}_4} \zeta_{\mathbf{k}_5} \zeta_{\mathbf{k}_6} \right\rangle = (2\pi)^3 \delta^{(3)}(\mathbf{k}_1 + \mathbf{k}_2 + \mathbf{k}_3 + \mathbf{k}_4 + \mathbf{k}_5 + \mathbf{k}_6) \times T_{\zeta}(\mathbf{k}_1, \mathbf{k}_2, \mathbf{k}_3, \mathbf{k}_4, \mathbf{k}_5, \mathbf{k}_6).
\]

Notice that, on the right-hand side of (17) through (19), we indicated a dependence from the direction of the wavevectors; in models of inflation where isotropy is preserved, the power spectrum and the bispectrum only depend on the moduli of the wave vectors. This will not be the case for the \( SU(2) \) model.

The \( \delta N \) formula [31, 128–130] will be employed

\[
\zeta(x, t) = N(x, t^*) - N(t^*, t) = \delta N(x, t),
\]

which holds if times \( t^* \) and \( t \) are chosen, respectively, on a flat and on a uniform density temporal slices (\( N \) is the number of e-foldings of inflation occurring between these two times). We employ a spatial metric \( g_{ij} = a^2(t)e^{-2\eta}(e^\eta)_{ij} \),

and at linear level the curvature perturbation corresponds to

\[
\zeta = -\Psi + H\dot{\delta}u,
\]

where \( \Psi \) is the fluctuation in the total energy density and \( \Psi \) is a scalar metric fluctuation. In the presence of a single scalar field \( \phi \), (20) is further expandable as

\[
\zeta(x, t) = \sum_n \frac{N^{(n)}(t^*, t)}{n!} (\delta \phi(x, t^*))^n,
\]

where \( N^{(n)} \) is the partial derivative of the e-folding number w.r.t. \( \phi \) on the initial hypersurface \( t^* \).

If we apply (21) to the inflaton + \( SU(2) \) vector model, we have

\[
\zeta(x, t) = N_\phi \delta \phi + N_\mu^\mu \delta A_\mu^\mu + \frac{1}{2} N_{\phi \phi} \delta (\delta \phi)^2 + \frac{1}{2} N_{\mu \nu} \delta A_\mu^\lambda \delta A_\nu^\lambda
\]

\[
+ N_{\mu \alpha} \delta \phi \delta A_\mu^\alpha + \frac{1}{3!} N_{\phi \phi \phi} \delta (\delta \phi)^3 + \frac{1}{3!} N_{\mu \nu \alpha} \delta A_\mu^\lambda \delta A_\nu^\beta \delta A_\alpha^\gamma
\]

\[
+ \frac{1}{3} N_{\phi \phi \phi \phi} \delta (\delta \phi)^4 + \frac{1}{3!} N_{\mu \nu \alpha \beta} \delta A_\mu^\lambda \delta A_\nu^\beta \delta A_\alpha^\gamma \delta A_\beta^\lambda + \cdots,
\]

where now

\[
N_\phi \equiv \left( \frac{\partial N}{\partial \phi} \right)_t, \quad N_\mu^\mu \equiv \left( \frac{\partial N}{\partial A_\mu^\mu} \right)_t, \quad N_{\phi \phi} \equiv \left( \frac{\partial^2 N}{\partial \phi^2} \right)_t,
\]

and so on for higher order derivatives.

On a general ground, given the fact that the temporal modes can always be expressed in terms of the longitudinal modes, (22) can be rewritten by retaining only the spatial part for the vector field fluctuations (see also [96]).

Our plan is to show the derivation the correlation functions of \( \zeta \) from the ones of \( \delta \phi \) and \( \delta A_\mu^\alpha \), after a replacement of the \( \delta N \) expansion (22) in (17) through (19).

The correlation functions can be evaluated using the Schwinger-Keldysh formula [48–52]

\[
\langle \Omega(\Theta(t)|\Omega) \rangle = \langle 0 \left| \mathcal{T}e^{-i\int_0^\Lambda H(t')dt'} \right| \Theta(t) \left[ T(e^{-i\int_0^\Lambda H(t')dt'}) \right] 0 \rangle.
\]
where, on the left-hand side, the operator Θ and the vacuum Ω are in the interacting theory whereas, on the right-hand side, all operators are in the so-called “interaction picture”, that is, they can be treated as free fields (the Fourier expansion in (13) thus apply), and |0⟩ is the free theory vacuum.

When calculating the spectra of ζ, the perturbative expansions in (22) and (24) will be carried out to only include tree-level contributions, neglecting higher order “loop” terms, either classical, that is, from the in-in formula (we call these “Abelian”, being them retrievable in the SU(2) case), and by (“non-Abelian”) terms arising from the Schwinger-Keldysh series. Assuming that the SU(2) coupling g is “small” and that we are dealing with “small” fluctuations in the fields and given the fact that a slow-roll regime is being assumed, it turns out that it is indeed safe for the two expansions to be truncated at tree-level.

The correlation functions of ζ will then result as the sum of scalar, vector and (scalar and vector) mixed contributions. As to the vector part, this will be made up of terms that are merely generated by the δN expansion, that is, they only include the zeroth order of the in-in formula (we call these terms “Abelian”, being them retrievable in the U(1) case), and by (“non-Abelian”) terms arising from the Schwinger-Keldysh operator expansion beyond zeroth order, that is, from the gauge fields self-interactions.

Let us now discuss the level of generality of the results we will present in the next sections, w.r.t. the choice of a specific Lagrangian.

The expression for the Abelian contributions provided in Sections 4.1 and 4.2.1 apply to any SU(2) model of gauge interactions with no direct coupling between scalar and vector fields (extra terms would be otherwise needed in (33) and (34)). The next stage in the Abelian contributions computation would be to explicitate the derivatives of the e-foldings number and the wavefunctions of the fields: they both depend on the equations of motion of the system, therefore the fixing of a specific model is required at this point. As to the non-Abelian contributions, the results in (42) and (43) are completely general except for assuming, again, that no direct vector-scalar field coupling exists. The structure of (52) and (55) is instead due to the choice of a non-Abelian gauge group. The expressions of the anisotropy coefficients I_n and L_n in (52) and (55) depend on the specific Abelian gauge group (for SU(2) one of the I_n is given in (54)).

Finally, the specific expressions of the isotropic functions F_n (a sample of which is shown in (53)) and G_n were derived considering the Lagrangian (12) with f = 1 and the eigenfunctions for the vector bosons provided in (15) and (16).

4.1. The Power Spectrum. The power spectrum of ζ can be straightforwardly derived at tree-level, using the δN expansion (22), from the inflaton and the vector fields power spectra

\[ P_\zeta(k) = P_\zeta^{iso}(k) \left[ 1 + g^{ab} \left( \hat{k} \cdot \hat{N}_a \right) \left( \hat{k} \cdot \hat{N}_b \right) + i s^{ab} \hat{k} \cdot \left( \hat{N}_a \times \hat{N}_b \right) \right], \]  

which generalizes the results of [96] for the U(1) case.

The isotropic part of the previous expression has been factorized in

\[ P_\zeta^{iso}(k) = N_\zeta^2 P_\psi(k) + \left( \hat{N}_c \cdot \hat{N}_d \right) P_{cd}^{ab}, \]  

where we have defined the following combinations

\[ P_{ab}^{ab} = \left( \frac{1}{2} \right) \left( P_R^{ab} + P_L^{ab} \right), \]

from the power spectra for the right, left and longitudinal polarization modes

\[ P_R^{ab} = \delta_{ab} \delta A_R^a(k,t^+) \delta A_R^b(k,t^+), \]
\[ P_L^{ab} = \delta_{ab} \delta A_L^a(k,t^+) \delta A_L^b(k,t^+), \]
\[ P_{long}^{ab} = \delta_{ab} \delta A_{long}^a(k,t^+) \delta A_{long}^b(k,t^+). \]

The anisotropic parts are weighted by the coefficients

\[ g^{ab} = \frac{N^a N^{ab} \left( P_{long}^{ab} - P_{cd}^{ab} \right)}{N_\zeta^2 P_\psi + \left( \hat{N}_c \cdot \hat{N}_d \right) P_{cd}^{ab}}, \]
\[ s^{ab} = \frac{N^a N^{ab} P_{cd}^{ab}}{N_\zeta^2 P_\psi + \left( \hat{N}_c \cdot \hat{N}_d \right) P_{cd}^{ab}}, \]

(where a sum is intended over indices c and d but not over a and b). Equation (26) can also be written as

\[ P_\zeta^{iso}(k) = N_\zeta^2 P_\psi \left[ 1 + \beta_{cd} \frac{P_{cd}^{ab}}{P_\phi} \right], \]  

after introducing the parameter

\[ \beta_{cd} = \frac{\hat{N}_c \cdot \hat{N}_d}{N_\zeta^2}. \]

Notice that what when we say “isotropic”, as far as the expression for the power spectrum is concerned, we simply mean “independent” of the direction of the wave vector. In this case instead, the vector bosons introduce three preferred spatial directions: the r.h.s. of (25) depends on their orientation w.r.t. the wave vector.

As expected, the coefficients g^{ab} and s^{ab} that weight the anisotropic part of the power spectrum are related to β_{cd}, that is, to the parameters that quantify how much the expansion of the universe is affected by the vector bosons compared to the scalar field.

Assuming no parity violation in the model, we have s^{ab} = 0; the parameters g^{ab} and β_{ab} are instead unconstrained. In the U(1) case and for parity conserving theories, (25) reduces to [96]

\[ P_\zeta(k) = P_\zeta^{iso}(k) \left[ 1 + g \left( \hat{k} \cdot \hat{n} \right) \right], \]  

where \hat{n} indicates the preferred spatial direction; also one can check that in this simple case, if P_\zeta ≃ P_\psi and P_{long} = kP_\zeta (k ≠ 1), the relation g = (k - 1)β/(1 + β) holds, where
$$\beta \equiv (N_0/N_\phi)^2$$ (the anisotropy coefficient $g$ is not to be confused with the SU(2) coupling constant $g_c$). If it is safe to assume $|g| \ll 1$ (see discussion following (1) and references [73, 74]), a similar upper bound can also be placed on $\beta$.

In the case where more than one special directions exists, as in the SU(2) model, no such analysis on the anisotropy data has been so far carried out, the $g^a$ parameters cannot then be constrained, unless assuming that the three directions converge into a single one; in that case a constraint could be placed on the sum $|g| \equiv |\sum_a g^a|$, where $a = 1, 2, 3$ and $P_\ell(k) = P^{\text{iso}}_\ell(k)[1 + g^{(k \cdot n_a)}]$.

4.2. Higher-Order Correlators. We will present the results for the tree-level contributions to the bispectrum and to the trispectrum of $\zeta$.

These can be classified in two categories, that we indicate as “Abelian” and “non-Abelian”. The former are intended as terms that merely arise from the $dN$ expansion and are thus retrievable in the Abelian case; the latter are derived from the linear and quadratic expansions (in terms of the gauge bosons interaction Hamiltonian) of the Schwinger-Keldysh formula and are therefore peculiar to the non-Abelian case.

We are going to provide both types of contributions, in preparation for discussing and comparing their magnitudes later on in Section 5.

4.2.1. Abelian Contributions. By plugging the $dN$ expansion (22) in (18) and (19), we have

\[
B_\ell(k_1, k_2, k_3) \\
\geq \frac{1}{2}N_0^2N_\phi\left[ P_\phi(k_1)P_\phi(k_2) + \text{perms.} \right] \\
+ \frac{1}{2}N_0^2N_\phi^iN_\phi^{ij}\left[ \Pi^{(i)}_{ik}(k_1)\Pi^{(j)}_{kj}(k_2) + \text{perms.} \right] \\
+ \frac{1}{2}N_0^2N_\phi^{ij}N_\phi^j\left[ P_\phi(k_1)\Pi^{(ij)}_{kj}(k_2) + \text{perms.} \right] \\
+ N_0N_\phi^jB_\phi(k_1, k_2, k_3),
\]

for the bispectrum (see also [96]) and

\[
T_\ell(k_1, k_2, k_3, k_4) \\
\geq N_0^2T_\phi(k_1, k_2, k_3, k_4) \\
+ N_0^2N_\phi\left[ P_\phi(k_1)B_\phi\left( \left| k_1 + k_2, k_3, k_4 \right| \right) + \text{perms.} \right] \\
+ N_0^2N_\phi^{ij}N_\phi^{ij}\left[ P_\phi^{ij}(k_3)B_\phi\left( k_1, k_2, \left| k_3 + k_4 \right| \right) + \text{perms.} \right] \\
+ N_0^2N_\phi^{ij}N_\phi^{ij}\left[ P_\phi^{ij}(k_1)P_\phi^{ij}(k_2)P_\phi\left( \left| k_1 + k_3 \right| \right) + \text{perms.} \right] \\
+ N_0^2N_\phi^{ij}N_\phi^{ij}\left[ P_\phi^{ij}(k_1)P_\phi^{ij}(k_2)P_\phi\left( \left| k_1 + k_3 \right| \right) + \text{perms.} \right] \\
+ N_0^2N_\phi^{ij}N_\phi^{ij}\left[ P_\phi^{ij}(k_1)P_\phi^{ij}(k_2)P_\phi\left( \left| k_1 + k_3 \right| \right) + \text{perms.} \right] \\
+ N_0^2N_\phi^{ij}N_\phi^{ij}\left[ P_\phi^{ij}(k_1)P_\phi^{ij}(k_2)P_\phi\left( \left| k_1 + k_3 \right| \right) + \text{perms.} \right] \\
\times \left[ P^{\text{abc}}_{ik}(k_1)P^{\text{abc}}_{jl}(k_2)P_\phi\left( \left| k_1 + k_3 \right| \right) + \text{perms.} \right] \\
+ N_0^2N_\phi^{ij}N_\phi^{ij}\left[ P_\phi(k_1)P_\phi(k_2)P_\phi^{ij}(k_3) + \text{perms.} \right] \\
+ N_0^2N_\phi^{ij}N_\phi^{ij}\left[ P_\phi(k_1)P_\phi(k_2)P_\phi^{ij}(k_3) + \text{perms.} \right] \\
+ N_0^2N_\phi^{ij}N_\phi^{ij}\left[ P_\phi(k_1)P_\phi(k_2)P_\phi^{ij}(k_3) + \text{perms.} \right] \\
\times \left[ P^{\text{abc}}_{ik}(k_1)P^{\text{abc}}_{jl}(k_2)P_\phi\left( \left| k_1 + k_3 \right| \right) + \text{perms.} \right] \\
\times \left[ P^{\text{abc}}_{ik}(k_1)P^{\text{abc}}_{jl}(k_2)P_\phi\left( \left| k_1 + k_3 \right| \right) + \text{perms.} \right] \\
\times \left[ P^{\text{abc}}_{ik}(k_1)P^{\text{abc}}_{jl}(k_2)P_\phi\left( \left| k_1 + k_3 \right| \right) + \text{perms.} \right] \\
\times \left[ P^{\text{abc}}_{ik}(k_1)P^{\text{abc}}_{jl}(k_2)P_\phi\left( \left| k_1 + k_3 \right| \right) + \text{perms.} \right]
\]

for the trispectrum (see also [97]).

Let us now provide some definition for the quantities introduced in the previous equations

\[
\Pi_{ij}^{(j)}(k) = T_{ij}^{\text{even}}(k)P_{+}^{ij} + iT_{ij}^{\text{odd}}(k)P_{-}^{ij} + T_{ij}^{\text{long}}(k)P_{\text{long}}^{ij}
\]

where

\[
T_{ij}^{\text{even}}(k) \equiv e^j(\hat{k})e^{iL}(\hat{k}) + e^j(\hat{k})e^{iR}(\hat{k}),
\]

\[
T_{ij}^{\text{odd}}(k) \equiv i\left[ e^j(\hat{k})e^{iL}(\hat{k}) - e^i(\hat{k})e^{iR}(\hat{k}) \right],
\]

\[
T_{ij}^{\text{long}}(k) \equiv e^i(\hat{k})e^{iR}(\hat{k}).
\]

The polarization vectors are $e^i(\hat{k}) \equiv (1/\sqrt{2})(\cos \theta \cos \phi - i \sin \phi, \cos \theta \sin \phi + i \cos \phi, -\sin \theta, \cos \theta)$ and $e^j(\hat{k}) = \hat{k} = (\sin \theta \cos \phi, \sin \theta \sin \phi, \cos \theta)$, from which we have

\[
T_{ij}^{\text{even}}(k) = \delta_{ij} - \hat{k}_i\hat{k}_j,
\]

\[
T_{ij}^{\text{odd}}(k) = e_{ij}\hat{k}_k,
\]

\[
T_{ij}^{\text{long}}(k) = \hat{k}_i\hat{k}_j.
\]

The purely scalar terms in (33)-(34) are already known from the literature: in single-field slow-roll inflation $P_\phi = H_*^2/2k^3$, where $H_*$ is the Hubble rate evaluated at horizon exit; the bispectrum and the trispectrum of the scalar field ($B_\phi$ and $T_\phi$) can be found in [9–11, 38, 131] (they were also reported in [102, (11) and (12)])). As to the mixed (scalar-vector) terms, they can be ignored if one considers a Lagrangian where there is no direct coupling between the inflaton and the gauge bosons and where slow-roll assumptions are introduced for the fields [see [102, Section 4] for a complete discussion on this]. Let us then look at the (purely) vector
4.2.2. Non-Abelian Contributions.  

$$B_{\ell} \left( \tilde{k}_1, \tilde{k}_2, \tilde{k}_3 \right) \supset 1/2 N_{a}^{i} N_{b}^{j} N_{c}^{k} \Pi_{ij}^{kl} \left( \tilde{k}_1 \right) \Pi_{ji}^{bd} \left( \tilde{k}_2 \right) = M_{k}^{j} N_{cd}^{kl} M_{d}^{l} \quad \text{(38)}$$

$$T_{\ell} \left( \tilde{k}_1, \tilde{k}_2, \tilde{k}_3, \tilde{k}_4 \right) \supset N_{a}^{i} N_{b}^{j} N_{c}^{k} N_{d}^{l} T_{ijkl}^{abcd} \left( \tilde{k}_1, \tilde{k}_2, \tilde{k}_3, \tilde{k}_4 \right) + N_{a}^{i} N_{b}^{j} N_{c}^{k} N_{d}^{l} B_{ijkl}^{abc} \left( \tilde{k}_1, \tilde{k}_2, \tilde{k}_3 + \tilde{k}_4 \right) + \text{perms.} \quad \text{(39)}$$

where

$$M_{k}^{j} \left( \tilde{k} \right)$$

$$= N_{a}^{i} P_{ik}^{ac} \left( \tilde{k} \right)$$

$$= P_{ac}^{i} \left( k \right) \left[ \delta_{ik} N_{a}^{i} + P_{ac}^{i} \left( k \right) \tilde{k} \cdot N_{a}^{i} + i q^{ac} \left( k \right) \left( \tilde{k} \times N_{a}^{i} \right) \right].$$

$$L_{ij}^{kl} \left( \tilde{k} \right)$$

$$= N_{cd}^{ij} P_{kl}^{df} \left( \tilde{k} \right) N_{e}^{kl}$$

$$= P_{+}^{i} \left( k \right) \left[ N_{cd}^{ij} \cdot N_{f}^{kl} + P_{+}^{i} \left( k \right) \left( \tilde{k} \cdot N_{cd}^{ij} \right) \left( \tilde{k} \cdot N_{f}^{kl} \right) + i q^{df} \left( k \right) \tilde{k} \cdot N_{cd}^{ij} \times N_{f}^{kl} \right].$$

(40)

In the previous equations, we defined

$$p_{ac}^{i} \left( k \right) \equiv \frac{P_{ac}^{i} - P_{+}^{i}}{P_{ac}^{i}}$$

$$q^{ac} \left( k \right) \equiv \frac{P_{+}^{i}}{P_{ac}^{i}},$$

with $N_{a}^{i} \equiv \left( N_{a}^{i}, N_{a}^{i}, N_{a}^{i} \right)$ and $N_{cd}^{ij} \equiv \left( N_{cd}^{ij}, N_{cd}^{ij}, N_{cd}^{ij} \right)$.

Notice that, as for the power spectrum (25), also in (38)-(39) the anisotropic parts of the expressions are weighted by coefficients that are proportional either to $P_{-}$ or to $(P_{\text{long}} - P_{+})$. When these two quantities are equal to zero, the (Abelian) bispectrum and trispectrum are therefore isotropized. $P_{-} = 0$ in parity conserving theories, like the ones we have been describing. According to the parametrization (16) of the longitudinal mode, we have $P_{\text{long}} - P_{+} = \left( \left| n \left( x \right) \right|^{2} - 1 \right) P_{+}.$

4.2.2. Non-Abelian Contributions. We list the non-Abelian terms for the bispectrum

$$B_{\ell} \left( \tilde{k}_1, \tilde{k}_2, \tilde{k}_3 \right) \supset N_{a}^{i} N_{b}^{j} N_{c}^{k} B_{ijkl}^{abc} \left( \tilde{k}_1, \tilde{k}_2, \tilde{k}_3 \right),$$

and for the trispectrum

$$T_{\ell} \left( \tilde{k}_1, \tilde{k}_2, \tilde{k}_3, \tilde{k}_4 \right)$$

$$= N_{a}^{i} N_{b}^{j} N_{c}^{k} N_{d}^{l} T_{ijkl}^{abcd} \left( \tilde{k}_1, \tilde{k}_2, \tilde{k}_3, \tilde{k}_4 \right)$$

The computation of the vector bosons spectra

$$\left\langle \delta A_{+}^{i} \delta A_{+}^{j} \delta A_{-}^{i} \right\rangle = \delta^{(3)} \left( \tilde{k}_1 + \tilde{k}_2 + \tilde{k}_3 \right) B_{ijkl}^{abc},$$

$$\left\langle \delta A_{+}^{i} \delta A_{+}^{j} \delta A_{+}^{k} \right\rangle = \delta^{(3)} \left( \tilde{k}_1 + \tilde{k}_2 + \tilde{k}_3 + \tilde{k}_4 \right) T_{ijkl}^{abcd},$$

will be reviewed in this section. This requires the expansion of the in-in formula up to second order in the interaction Hamiltonian

$$\left\langle \Theta \left( \eta^{+} \right) \right\rangle$$

$$i \left\langle T \left[ \Theta \int_{-\infty}^{\eta^{+}} d\eta' \left( H_{\text{int}}^{+} \left( \eta' \right) - H_{\text{int}}^{+} \left( \eta' \right) \right) \right] \right\rangle$$

$$+ \left( -i \right)^{2} \left\langle T \left[ \Theta \int_{-\infty}^{\eta^{+}} d\eta' \left( H_{\text{int}}^{+} \left( \eta' \right) - H_{\text{int}}^{+} \left( \eta' \right) \right) \times \int_{-\infty}^{\eta^{+}} d\eta'' \left( H_{\text{int}}^{+} \left( \eta'' \right) - H_{\text{int}}^{+} \left( \eta'' \right) \right) \right] \right\rangle.$$

(45)

The interaction Hamiltonian needs to be expanded up to fourth order in the fields fluctuations, that is, $H_{\text{int}} = H_{\text{int}}^{(3)} + H_{\text{int}}^{(4)},$ where

$$H_{\text{int}}^{(3)} = g e^{abc} g^{ijk} \left( \delta_{ij} B_{k}^{b} \delta B_{i}^{c} + g^{ijk} B_{k}^{b} \delta B_{j}^{c} \delta B_{i}^{d} \right),$$

$$H_{\text{int}}^{(4)} = g^{2} e^{abc} g^{ijk} g^{klm} \delta B_{k}^{b} \delta B_{i}^{c} \delta B_{j}^{d} \delta B_{l}^{e}.$$

(46)

To tree-level, the relevant diagrams are pictured in Figures 1 and 2. By looking at (46), we can see that there is a bispectrum diagram that is lower in terms of power of the $SU(2)$ coupling ($\sim g_{E}$) compared to the trispectrum ($\sim g_{C}^{2}$); as a matter of fact, for symmetry reasons that we are going to discuss later in this section, $g_{E}^{2}$ interaction terms are needed to provide a nonzero contributions to the bispectrum.
The propagators for “plus” and “minus” fields are
\[
\delta B_i^{a+} (\eta') \delta B_j^{b+} (\eta'') = \tilde{\Pi}_{ij}^{ab} (\eta', \eta'') \Theta (\eta'' - \eta') \\
+ \Pi_{ij}^{ab} (\eta', \eta''),
\]
\[
\delta B_i^{a-} (\eta') \delta B_j^{b-} (\eta'') = \tilde{\Pi}_{ij}^{ab} (\eta', \eta''),
\]
\[
\delta B_i^{a-} (\eta') \delta B_j^{b+} (\eta'') = \tilde{\Pi}_{ij}^{ab} (\eta', \eta''),
\]
\[
\delta B_i^{a+} (\eta') \delta B_j^{b-} (\eta'') = \tilde{\Pi}_{ij}^{ab} (\eta', \eta'').
\]
Equation (49) becomes
\[
\langle \zeta_{k_i} \zeta_{k_j} \zeta_{k_l} \rangle \supset N_i^a N_j^b N_l^c \delta \frac{\delta^3 (\vec{k}_i + \vec{k}_j + \vec{k}_l)}{a^3 (\eta^* x^*)} \\
\times \left[ \int d\eta^a (\eta) \tilde{\Pi}_{mn} (\vec{k}_i) \tilde{\Pi}_{ij} (\vec{k}_j) \tilde{\Pi}_{kl} (\vec{k}_l) \right] \\
\times \left( g e^{abc} k_{1l} + g^2 e^{da} e^{d} e^{bc} B_{ij} \right) + \text{perms. + c.c.}
\]
Even before performing the time integration, one realizes that, because of the antisymmetric properties of the Levi-Civita tensor, the \(-g_e\) contribution on the r.h.s. of (51) is equal to zero once the sum over all the possible permutations has been performed. The vector bosons bispectrum is therefore proportional to \(g_e^2\). The final result from (51) has the following form
\[
\langle \zeta_{k_i} \zeta_{k_j} \zeta_{k_l} \rangle \supset (2\pi)^3 \delta (\vec{k}_i + \vec{k}_j + \vec{k}_l) g_e^2 H^2 \\
\times \sum_n F_n (k_i, \eta^*) I_n (\vec{k}_i \cdot \hat{k}_j, \vec{A}_i \cdot \hat{A}_j, \vec{k}_i \cdot \hat{A}_j),
\]
where the \(F_n\)'s are isotropic functions of time and of the moduli of the wave vectors \((i = 1, 2, 3)\) and the \(I_n\)'s are anisotropic coefficients. The sum in the previous equation is taken over all possible combinations of products of three polarization indices, that is, \(n \in (EEE, EEL, EIE, \ldots, III)\), where \(E\) stands for “even”, \(I\) for “longitudinal”. The complete expressions for the terms appearing in the sum are quite lengthy (see [101, Section 4.2]). As an example, we report one of these terms
\[
F_{III} = -n^E (x^*) \frac{1}{24 k_i k_j k_l x^2} \\
\times \left[ A_{EEE} + (B_{EEE} \cos x^* + C_{EEE} \sin x^*) E_i x^* \right],
\]
\[
I_{III} = e^{a_i c^j} e^{a^i c^j} \\
\times \left[ \left( \hat{k}_i \cdot \vec{N}^a \right) \left( \hat{k}_j \cdot \vec{N}^b \right) \left( \hat{k}_l \cdot \vec{N}^c \right) \left( \hat{k}_i \cdot \hat{k}_j \right) \left( \hat{k}_j \cdot \hat{k}_l \right) \right. \\
\times \left( \hat{k}_i \cdot \hat{A}^c \right) - \left( \hat{k}_j \cdot \vec{N}^a \right) \left( \hat{k}_k \cdot \vec{N}^b \right) \left( \hat{k}_l \cdot \hat{A}^c \right) \\
\left. \times (1 \rightarrow 3) + (2 \rightarrow 3) \right],
\]
where \(A_{EEE}, B_{EEE}\) and \(C_{EEE}\) are functions of \(x^*\) and of the momenta \(k_i = |\vec{k}_i|\) (they are all reported in [101, Appendix C]), \(E_i\) is the exponential-integral function and \(i \leftrightarrow j\) means “exchange \(\vec{k}_i\) with \(\vec{k}_j\)”. As we will discuss in more details in Section 6, one of the more interesting features of these models is that the bispectrum and the trispectrum turn out to have an amplitude that is modulated by the preferred directions that break statistical isotropy.
Let us now move to the trispectrum. Again, we count two different kinds of contributions, the first from $\sim g_s$ and the second from $\sim g_v^2$ interaction terms, respectively in $H^{(3)}_{\text{int}}$ and $H^{(4)}_{\text{int}}$. The former produce vector-exchange diagrams, the latter are represented by contact-interaction diagrams (see Figure 2). Their analytic expressions are different, but they both have a structure similar to (52)

$$\langle \zeta_{k_1} \zeta_{k_2} \zeta_{k_3} \zeta_{k_4} \rangle \supset (2\pi)^3 \delta^{(3)}(\vec{k}_1 + \vec{k}_2 + \vec{k}_3 + \vec{k}_4)g_s^2H^2_{\ast}$$

and

$$\sum_n G_n(k_1, k_2, k_3, \eta^*) L_n(\vec{k}_1 \cdot \vec{A}_i, \vec{k}_2 \cdot \vec{A}_j, \vec{k}_3 \cdot \vec{A}_k, \vec{k}_4 \cdot \vec{A}_l),$$

where we define $k_1 \equiv |\vec{k}_1|$ and $k_\perp \equiv |\vec{k}_1 - \vec{k}_4|$ (see [102, Sections 5.2.1 and 5.2.2] for the explicit expressions of the functions $G_n$ and $L_n$).

5. Amplitude of non-Gaussianity: $f_{NL}$ and $\tau_{NL}$

In this paper, we use the following definitions for the non-Gaussianity amplitudes

$$6^2 f_{NL} = \frac{B_t(\vec{k}_1, \vec{k}_2, \vec{k}_3)}{P_{\text{iso}}(k_1)P_{\text{iso}}(k_2)} + \text{perms},$$

$$\tau_{NL} = \frac{2T_t(\vec{k}_1, \vec{k}_2, \vec{k}_3, \vec{k}_4)}{P_{\text{iso}}(k_1)P_{\text{iso}}(k_2)P_{\text{iso}}(k_1) + 23 \text{ perms}}.$$  (55)

The choice of normalizing the bispectrum and the trispectrum by the isotropic part of the power spectrum, instead of using its complete expression $P_t$, is motivated by the fact that the latter would only introduce a correction to the previous equations proportional to the anisotropy parameter $g_s$, which is a small quantity.

The parameters $f_{NL}$ and $\tau_{NL}$ receive contributions both from scalar (“$s$”) and from vector (“$v$”) fields

$$f_{NL} = f_{NL}^{(s)} + f_{NL}^{(v)},$$

$$\tau_{NL} = \tau_{NL}^{(s)} + \tau_{NL}^{(v)}.$$  (58)

The latter can again be distinguished into Abelian $(A)$ and non-Abelian $(NA)$

$$f_{NL}^{(v)} = f_{NL}^{(A)} + f_{NL}^{(NA)},$$

$$\tau_{NL}^{(v)} = \tau_{NL}^{(A)} + \tau_{NL}^{(NA)} + \tau_{NL}^{(NA)} + \tau_{NL}^{(NA)}.$$  (60)

The expression of the number of e-foldings depends on the specific model and, in particular, on the mechanism of production of the fluctuations. Two possibilities have been described in Section 2. For vector inflation we have

$$N_a^i = \frac{A^i_t}{2m^2}, \quad N_{ab} = \frac{\delta_{ab}\delta^g}{2m^2}.$$  (61)

(see [101, Appendix B] for their derivation). In the vector curvaton model the same quantities become [96, 101]

$$N_a^i = \frac{2}{3} r \frac{A^i_t}{\sum_b |A^b|^2}, \quad N_{ab} = \frac{1}{3} r \frac{\delta_{ab}\delta^{ij}}{\sum_c |A^c|^2}.$$  (62)

Neglecting tensor and gauge indices, the expressions above can be simplified as $N_a \simeq A/m^2$ and $N_{AA} \simeq 1/m^2$ in vector inflation, $N_A \simeq r/A$ and $N_{AA} \simeq r/A^2$ in the vector curvaton model. Also we have $N_{AAA} = 0$ in vector inflation and $N_{AAA} \simeq r/A^3$ in vector curvaton.

We are now ready to provide the final expressions for the amplitudes: in Table 1 we list all the contributions to $f_{NL}$,

The quantities involved in the amplitude expressions are \( g, \beta, r, \epsilon_{\phi}, g_{\phi}, m_P/H, A/m_P \) and \( A/H \). We already know that \( g \) and \( \beta \) are to be considered smaller than one (see discussion after (32)). Similarly, as mentioned after (3), \( r \) has to remain small at least until inflation ends so as to attain an “almost isotropic” expansion. The slow-roll parameter \( \epsilon_{\phi} \) and the SU(2) coupling \( g_{\phi} \) are small, respectively, to allow the inflaton to slowly roll down its potential and for perturbation theory to be valid. The ratio \( m_P/H \) is of order \( 10^4 \) (assuming \( \epsilon_{\phi} \sim 10^{-1} \)). Finally, \( A/m_P \) and \( A/H \) have no stringent bounds. A reasonable choice could be to assume that the expectation value of the gauge fields is no larger than the Planck mass, that is, \( A/m_P \leq 1 \). As to the \( A/H \) ratio, different possibilities are allowed, including the one where it is of order one (see [99, Section 6 and Appendix A] for a discussion on this).

Let us now compare the different amplitude contributions. The ratios between scalar and vector contributions are shown in Table 3 for the bispectrum and Table 4 for the trispectrum. We can observe that the dominance of a given contribution w.r.t. another one very much depends on the selected region of parameter space. It turns out that it is allowed for the vector contributions to be larger than the scalar ones and also for the non-Abelian contributions to be larger than the Abelian ones. This is discussed more in details in [99, Section 6]. An interesting point is, for
instance, the following: ignoring tensor and gauge indices, the ratio \( g_c A/H \), that appears in many of the Tables entries, is a quantity smaller than one; if we consider the different configurations identified by gauge and vector indices, we realize that this is not always true, in fact the value of this ratio can be \( \gg 1 \) in some configurations.

Finally, it is interesting to compare bispectrum and trispectrum amplitudes (see Table 5). Again, it is allowed for the ratios appearing in Table 5 to be either large or small, depending on the specific location within the parameter space of the theory. For instance, the combination of a small bispectrum with a large trispectrum is permitted. The latter is an interesting possibility: if the bispectrum was observably small, we could still hope the information about non-Gaussianity to be accessible thanks to the trispectrum.

Another interesting feature of this model is that the bispectrum and the trispectrum depend on the same set of quantities. If these correlation functions were independently observable small bispectrum with a large trispectrum is permitted. The space of the theory. For instance, the combination of a

6. Shape of Non-Gaussianity and Statistical Anisotropy Features

Studying the shape of non-Gaussianity means understanding the features of momentum dependence of the bispectrum and higher order correlators. If they also depend on variables other than momenta, it is important to determine how these other variables affect the profiles for any given momentum set-up. This is the case as far as the bispectrum and the trispectrum of the gauge fields are concerned, given the fact that they are functions, besides of momenta, also of a large set of angular variables (see (52) and (55)).

6.1. Momentum Dependence of the Bispectrum and Trispectrum Profiles. We show the study of the momentum dependence of the \( F_n \) and \( G_n \) functions in (52) and (55) first and then analyze the angular variables dependence of the spectra, once the momenta have been fixed in a given configuration. A natural choice would be to consider the configuration where the correlators are maximized.

The maxima can be easily determined for the bispectrum by plotting the isotropic functions \( F_n \) and \( G_n \) in terms of two of their momenta. These plots are provided in Figure 3, where the variables are \( s_2 \equiv k_3/k_1 \) and \( s_3 \equiv k_2/k_1 \). Each one of the plots corresponds to a single isotropic functions of the sum in (52). It is apparent that the maxima are mostly located in the so-called local region, that is, for \( k_1 \sim k_2 \gg k_3 \); three out of the eight graphs do not have their peaks in this configuration but, at the same time, they show negligible amplitudes compared to the “local” peaked graphs.

The situation is much more complex for the trispectrum, being the number of momentum variables larger than three \((k_1, k_2, k_3, k_4, k_{12}, k_{13}, k_{14}, k_{23}, k_{24}, k_{34})\). The momentum dependence of the isotropic functions can be studied by selecting different configurations for the tetrahedron made up by the four momentum vectors, in such a way as to narrow the number of independent momentum variables down to two. A list of possible configurations was presented in [43]. We consider two of them, the “equilateral” and the “specialized planar”.

In the equilateral configuration the four sides of the tetrahedron have the same length \((k_1 = k_2 = k_3 = k_4)\),

</tbody>
</table>
Figure 3: Plot of \( r_n \equiv \Theta(x_2 - x_3)\Theta(x_3 - 1 + x_2)x_2^2 R_n(x_2, x_3) \), where we define \( R_n = k_1^2 F_n \). The Heaviside step functions \( \Theta \) help restricting the plot domain to the region \((x_2, x_3)\) that is allowed for the triangle \( k_1 + k_2 + k_3 = 0 \) (in particular, we set \( x_3 < x_2 \)). We also set \( x^* = 1 \).

Therefore \( x \equiv k_{12}/k_1 \) and \( y \equiv k_{14}/k_1 \) can be chosen as variables for the plots. The plots of the isotropic functions of contact interaction and vector exchange contributions are provided in Figure 4. The former (c.i.) shows a constant behaviour in this configuration, being independent of \( k_{12} \) and \( k_{14} \). The latter (v.e.(I), v.e.(II) and v.e.(III)) diverge as \( k_{1i}^2 \) (\( i = 1, 2, \) and \( 3 \), resp., for the three plots) in the limit of a flat tetrahedron, that is, \((k_{1i}/k_1) \rightarrow 0\).

In the specialized planar configuration, the tetrahedron is flattened and, in addition to that, three of the six momentum variables are set equal to one another \((k_1 = k_3 = k_{14})\); this leaves two independent variables, which can be \( x \equiv k_2/k_1 \) and \( y \equiv k_{13}/k_1 \). There is a double degeneracy in this configuration, due to the fact that the quadrangle can have internal angles larger than or smaller/equal to \( \pi \), as we can see from the plus and minus signs in the expressions for \( k_{12} \) and \( k_{13} \) [43]

\[
\begin{align*}
k_{12}/k_1 &= \sqrt{1 + \frac{x^2 y^2}{2}} \pm \frac{xy}{2} \sqrt{(4 - x^2)(4 - y^2)}, \\
k_{13}/k_1 &= \sqrt{x^2 + y^2 - \frac{x^2 y^2}{2}} \pm \frac{xy}{2} \sqrt{(4 - x^2)(4 - y^2)}.
\end{align*}
\]
Figure 4: Plots of the isotropic functions appearing in the vector fields trispectrum (from (55)): c.i. is the contribution from contact-interaction diagrams, v.e.(I), v.e.(II), and v.e.(III) are the contributions from the vector-exchange diagrams. The equilateral configuration has been considered in this figure.

The two cases are plotted in Figures 5 and 6. Notice that divergences generally occur as \( x, y \to 0 \), as \( x \to y \) and \( (x, y) \to (2, 2) \).

6.2. Features and Level of Anisotropy. Statistical homogeneity and isotropy are considered characterizing features of the CMB fluctuations distribution, if one ignores the issues raised by the “anomalous” detections we presented in the introduction.

Homogeneity of the correlation functions equates translational invariance and hence total momentum conservation, as enforced by the delta functions appearing on the left-hand sides of (17) through (19). This invariance property can then be pictured as the three momentum vectors forming a closed triangle for the bispectrum and the four momenta arranged in a tetrahedron for the trispectrum (see Figure 7).

Statistical isotropy corresponds to invariance w.r.t. rotations in space of the momentum (for the power spectrum) and of the triangle or tetrahedron made up by the momenta, respectively for the bispectrum and the trispectrum. This symmetry can be broken, as it for example happens in the \( SU(2) \) case, by assuming the existence of preferred spatial directions in the early universe that might be revealed in the CMB observations. When this happens, the correlation functions are expected to be sensitive to the spatial orientation of the wave number or of the momenta triangles and tetrahedrons w.r.t. these special directions. Analogically, the bispectrum and the trispectrum will depend on the angles among the vector bosons and the wave vectors (besides the angles among the gauge bosons themselves), as shown in the coefficients appearing in (52) and (55). This implies that both the amplitude and the shape of bispectrum and trispectrum will be affected by these mutual spatial orientations. The modulation of the shapes by the directions that break statistical anisotropy was discussed with some examples both for the bispectrum and the trispectrum in our previous papers [101, 102]. These examples are here reported in Figures 8 and 9. In Figure 8 we show the plot of the vector
Figure 5: Plots of the contact interaction and of the vector-exchange contributions in the specialized planar configuration (plus sign).

contribution to the bispectrum of $\zeta$, properly normalized in the configuration

$$\vec{N}_3 = N_A(0, 0, 1),$$

$$\vec{N}_1 = \vec{N}_2 = N_A(\sin \theta \cos \phi, \sin \theta \sin \phi, \cos \theta),$$

where, the $(x, y, z)$ coordinate frame is chosen to be $\hat{k}_3 = \hat{x}$ and $\hat{k}_1 = \hat{k}_2 = \hat{z}$ and $\delta$ is the angle between $\vec{N}_{1,2}$ and $\hat{k}_3$.

In Figure 9 we provide a similar plot for the trispectrum, but in a different configuration

$$\vec{N}_2 \cdot \hat{k}_i = 0 \quad (i = 1, \ldots, 4)$$

$$\vec{N}_1 \cdot \hat{k}_1 = \cos \delta, \quad \vec{N}_1 \cdot \hat{k}_2 = 0,$$

$$\vec{N}_3 \cdot \hat{k}_2 = \cos \theta, \quad \vec{N}_3 \cdot \hat{k}_1 = 0.$$

In both examples, it is assumed for simplicity that the $\vec{N}_a$ have the same magnitude $N_A$ for all $a = 1, 2, 3$.

Another comment should be added concerning statistical anisotropy in the model. Notice that both the bispectrum and the trispectrum can be written as the sum of a purely isotropic and an anisotropic parts. The orders of magnitude of these two parts can, for instance, be read from Table 2 for the trispectrum: each one among $\tau_{NL}^{N_A}$, $\tau_{NL}^{A_1}$ and $\tau_{NL}^{A_2}$ provide the order of magnitude of the level of both their isotropic and anisotropic contributions, which are therefore comparable; $\tau_{NL}^{N_A}$ instead quantifies a purely anisotropic contribution which, as discussed in Section 5, can be comparable to the other three parts, if not the dominant one. A similar discussion applies to the bispectrum (see $f_{NL}^{A_1}$ and $f_{NL}^{N_A}$ in Table 1). We can then conclude that for the three and for the four point function, there is room in the parameter space of the theory for the anisotropic contributions to be as large as, or even larger than, the isotropic ones.

7. Conclusions

Motivated by the interest in models that combine non-Gaussianity and statistical anisotropy predictions for the CMB fluctuations, we have considered models of inflation where primordial vector fields effectively participate in the production of the curvature perturbations $\zeta$. More specifically, we have reviewed the computation of the correlation functions up to fourth order, considering an SU(2) vector
multipllet. The δN formalism was employed to express ζ in terms of the quantum fluctuations of all the primordial fields. The Schwinger-Keldysh formula was also used in evaluating the correlators.

The correlation functions result as the sum of scalar and vector contributions. The latter are of two kinds, “Abelian” (i.e., arising from the zeroth order terms in the Schwinger-Keldysh expansion) and “non-Abelian” (i.e., originating from the self-interactions of the vector fields). The bispectrum and the trispectrum final results are presented as a sum of products of isotropic functions of the momenta, $F_n$ and $G_n$ in (52) and (55), multiplied by anisotropy coefficients, $I_n$.

and \( L_\| \) in (52) and (55), which depend on the angles between the (gauge and wave) vectors.

The amplitude of non-Gaussianity has been presented through the parameters \( f_{\text{NL}} \) and \( \tau_{\text{NL}} \); in particular we have shown the dependence of these functions from the nonangular parameters of the theory. We have provided the comparisons among the different (scalar versus vector, Abelian versus non-Abelian) contributions to \( f_{\text{NL}} \) and \( \tau_{\text{NL}} \), noticing that any one of them can be the dominant contribution depending on the selected region of parameter space. In particular, we have stressed how the anisotropic contributions to the bispectrum and the trispectrum can overcome the isotropic parts. An interesting feature of these models is that the bispectrum and the trispectrum depend on the same set of parameters and their amplitudes are therefore strictly related to one another.

We have presented the shapes of both the bispectrum and the trispectrum. The isotropic functions appearing in their final expressions had been analyzed separately from their anisotropy coefficients. The bispectrum isotropic functions had been found to preferably show a local shape. The trispectrum ones had been plotted selecting equilateral and specialized planar configurations. The full expressions (i.e., complete of their anisotropy coefficients) of bispectrum and trispectrum have been presented in specific momenta configuration, in order to provide a hint of the modulation of shapes and amplitudes operated by anisotropy.

We have reviewed old and recent vector field models, indicating both their limits and achievements. We would like to stress that, in our view, the most promising features of these models consists in the possibility of providing both non-Gaussianity and statistical anisotropy predictions that are related to one another because of the fact that they share the same underlying theory. This might, at some point in the future, become a great advantage: measurements of non-Gaussianity and statistical anisotropy could be used to constrain statistical anisotropy or vice versa.
