Study of dynamic equations in time scale is a new area in mathematics. Time scale tries to build a bridge between real numbers and integers. Two derivatives in time scale have been introduced and called as delta and nabla derivative. Delta derivative concept is defined as forward direction, and nabla derivative concept is defined as backward direction. Within the scope of this study, we consider the method of obtaining parameters of regression equation of integer values through time scale. Therefore, we implemented least squares method according to derivative definition of time scale and obtained coefficients related to the model. Here, there exist two coefficients originating from forward and backward jump operators relevant to the same model, which are different from each other. Occurrence of such a situation is equal to total number of values of vertical deviation between regression equations and observation values of forward and backward jump operators divided by two. We also estimated coefficients for the model using ordinary least squares method. As a result, we made an introduction to least squares method on time scale. We think that time scale theory would be a new vision in least squares especially when assumptions of linear regression are violated.

1. Introduction

Although theoretical to a high extent, time scale tries to link a bridge between continuous and discrete analysis [1, 2]. Such calculations provide an integrated structure for the analysis of difference and differential equations [3–5]. Those equations [6, 7] have been applied in dynamic programming [8–13], neural network [10, 14, 15], economic modeling [10, 16], population biology [17], quantum calculus [18], geometric analysis [19], real-time communication networks [20], intelligent robotic control [21], adaptive sampling [22], approximation theory [13], financial engineering [12] on time scales, and switched linear circuits [23] among others.

This study deals with the estimation of parameters of regression equation by using least squares method through time scale.

The main purpose of least squares method is to minimize the sum of squared vertical deviations. For this, to find the coefficients in simple linear regression model \( Y = \beta_0 + \beta_1 x + \epsilon \), partial derivatives related to coefficients of equation \( Q = \sum_{i=1}^{n} \varepsilon_i^2 = \sum_{i=1}^{n} (y_i - \hat{\beta}_0 - \hat{\beta}_1 x_i)^2 \) are obtained and the stage takes place, in which normal equations are to be obtained by setting partial derivatives for each coefficient equal to zero.

And from normal equations, equation \( y_i = \hat{\beta}_0 + \hat{\beta}_1 x_i + e_i \), predictive model for (9) is obtained.

In statistics, least squares method is used in accordance with the known derivative definition when parameters of regression equation are obtained. In this study, time scale derivative definition is applied to the least squares method. In this regard, (9) simple linear regression model is considered and \( \hat{\beta}_0 \) and \( \hat{\beta}_1 \), estimators of \( \beta_0 \) and \( \beta_1 \) coefficients, are obtained in accordance with forward and backward jump operators. Different \( \hat{\beta}_0 \) and \( \hat{\beta}_1 \) parameter values are obtained, originating from forward and backward jump operators related to the \( \tilde{y} = \hat{\beta}_0 + \hat{\beta}_1 x \) simple linear regression equation. In cases when observation values are discrete, forward jump operator equation \( \sigma(t) = t + 1 \) and backward jump operator equation \( \rho(t) = t - 1 \) are taken.

The main approach in regression analysis is to minimize the sum of squared (vertical) deviations between actual and estimated values. This is a weighed method for regression
Abstract and Applied Analysis

analysis due to its statistical properties [24]. Here, the point which should be considered is that, since in least squares method, sum of squared vertical deviations is of interest, analysis would also operate accordingly. The issue of applying first and second derivatives should also be taken into consideration since the aim is to minimize the sum of squared vertical deviations.

The study consists of two main parts and in the last part takes place an implementation regarding time scale theory. Main parts discussed are time scale theory and simple linear regression, respectively. Time scale theory part includes an explanation of time scale derivative related to and the definitions of forward and backward jump operators. The other main part includes explanations to simple linear regression and continuous analysis under one model. Any relationship exists between $Y$ and $x$ level are random. Expected value of $Y$ at each $x$ level is defined by the equation

$$E(Y|X) = \beta_0 + \beta_1 X,$$

Figure 1: Variance of data from estimated regression model.

is defined for all $s \in U$, and called as nabla derivative of $f^\nabla(t)f$ at $t$ [16, 26].

Definition 3. Given the function $f : T \to R$ and $t \in T^\kappa \epsilon > 0$, there exists a neighborhood $U$ of $t$ ($U = (t-\delta, t+\delta)$) and $\delta > 0$ such that

$$\left| f(\sigma(t)) - f(\rho(t)) \right| - f^\nabla(t) \left[ \sigma(t) - \rho(t) \right] \leq \epsilon \left| \sigma(t) - \rho(t) \right|$$

for right-graininess function for all $x \in T, \mu_\sigma : T \to [0, \infty)$ is defined as follows:

$$\mu_\sigma (t) := \sigma(t) - t.$$  

Definition 4 (forward jump operator [1]). Let $T$ be a time scale. Then, for $t \in T$, forward jump operator $\sigma : T \to T$ is defined by

$$\sigma(t) := \min \{s \in T : s > t \}.$$  

Left-graininess function $\mu_\rho : T \to [0, \infty)$ is defined as follows:

$$\mu_\rho (t) := t - \rho(t).$$  

3. Simple Linear Regression Analysis

Simple linear regression [28, 29] consists of one single explanatory variable or independent variable or response variable or dependent variable. Let us take that a real relationship exists between $Y$ and $x$ and $Y$ values observed at each $x$ level are random. Expected value of $Y$ at each $x$ level is defined by the equation

$$E(Y \mid X) = \beta_0 + \beta_1 X,$$
where $\beta_0$ is the intercept and $\beta_1$ is the slope and $\beta_0$ and $\beta_1$ are unknown regression coefficients. Each $Y$ observation can be defined with the model below.

In equation

$$Y = \beta_0 + \beta_1x + \varepsilon$$  

(9)

$\varepsilon$ is the random error term with zero mean constitution of (unknown) variance $\sigma^2$.

Take $n$ binary observations of $(x_1, y_1), (x_2, y_2), \ldots, (x_n, y_n)$. Figure 1 shows the distribution diagram of observed values and the estimated regression line. Estimators of $\beta_0$ and $\beta_1$ would pass the "best line" through the data. German scientist Karl Gauss (1777–1855) made a suggestion in estimation of parameters $\beta_0$ and $\beta_1$ in (9) to minimize the sum of squared vertical deviations in Figure 1.

This criterion used in estimation of regression parameters is the least squares method. By using (9), $n$ observations in the sample can be defined as follows:

$$y_i = \beta_0 + \beta_1x_i + e_i, \quad i = 1, 2, \ldots, n$$  

(10)

and sum of squared deviations of observations from the actual regression line is as follows:

$$Q = \sum_{i=1}^{n} e_i^2 = \sum_{i=1}^{n} (y_i - \beta_0 - \beta_1x_i)^2.$$  

(11)

Least square estimators of $\beta_0$ and $\beta_1$ are $\hat{\beta}_0$ and $\hat{\beta}_1$, which may be calculated as follows:

$$\frac{\partial Q}{\partial \beta_0} \mid \hat{\beta}_0, \hat{\beta}_1 = -2\sum_{i=1}^{n} (y_i - \hat{\beta}_0 - \hat{\beta}_1x_i) = 0, \quad (12)$$

$$\frac{\partial Q}{\partial \beta_1} \mid \hat{\beta}_0, \hat{\beta}_1 = -2\sum_{i=1}^{n} (y_i - \hat{\beta}_0 - \hat{\beta}_1x_i)x_i = 0. \quad (12)$$

When these two equations are simplified

$$n\hat{\beta}_0 + \hat{\beta}_1 \sum_{i=1}^{n} x_i = \sum_{i=1}^{n} y_i,$$  

$$\hat{\beta}_0 \sum_{i=1}^{n} x_i + \hat{\beta}_1 \sum_{i=1}^{n} x_i^2 = \sum_{i=1}^{n} y_ix_i.$$  

(13)

These equations may be called as normal equations of least squares.

Thus, estimated regression line will be as follows:

$$\hat{y} = \hat{\beta}_0 + \hat{\beta}_1x.$$  

(14)

Each observation pair is provided with the relation below:

$$y_i = \hat{\beta}_0 + \hat{\beta}_1x_i + e_i, \quad i = 1, 2, \ldots, n.$$  

(15)

where $e_i = y_i - \hat{y}_i$: residuals; $y_i$: observation values; $\hat{y}_i$: estimated $y_i$ values.

### 4. Ordinary Least Square Method

#### 4.1. Normal Equations

These include normal situation and formula values of $\tilde{\beta}_0$ and $\tilde{\beta}_1$ estimators for forward and backward operators.

Normal equations in normal (usual) situations

$$n\tilde{\beta}_0 + \tilde{\beta}_1 \sum_{i=1}^{n} x_i = \sum_{i=1}^{n} y_i,$$  

$$\tilde{\beta}_0 \sum_{i=1}^{n} x_i + \tilde{\beta}_1 \sum_{i=1}^{n} x_i^2 = \sum_{i=1}^{n} y_ix_i.$$  

(16)

Time scale normal equations (forward jump operator)

$$n\tilde{\beta}_0 + \frac{n}{2} + \tilde{\beta}_1 \sum_{i=1}^{n} x_i = \sum_{i=1}^{n} y_i,$$  

$$\tilde{\beta}_0 \sum_{i=1}^{n} x_i + \tilde{\beta}_1 \sum_{i=1}^{n} x_i^2 + \frac{\sum_{i=1}^{n} x_i^2}{2} = \sum_{i=1}^{n} y_ix_i.$$  

(17)

$$\tilde{\beta}_0 = -\left(\sum_{i=1}^{n} x_i^2 + \sum_{i=1}^{n} x_i \sum_{i=1}^{n} x_i^2 - 2 \sum_{i=1}^{n} x_i \sum_{i=1}^{n} x_i^2 y_i \right) + 2 \sum_{i=1}^{n} y_i \sum_{i=1}^{n} x_i^2$$  

$$\times \left(\left(-\sum_{i=1}^{n} x_i^2 + \left(\sum_{i=1}^{n} x_i^2 \right)^2 \right)^{-1}\right).$$

$$\tilde{\beta}_1 = \left(\sum_{i=1}^{n} x_i^2 - 2n \sum_{i=1}^{n} x_i y_i - \sum_{i=1}^{n} x_i^2 \right) + 2 \sum_{i=1}^{n} y_i \sum_{i=1}^{n} x_i^2$$  

$$\times \left(\left(-\sum_{i=1}^{n} x_i^2 + \left(\sum_{i=1}^{n} x_i^2 \right)^2 \right)^{-1}\right).$$

Time scale normal equations (backward jump operator)

$$n\tilde{\beta}_0 - \frac{n}{2} + \tilde{\beta}_1 \sum_{i=1}^{n} x_i = \sum_{i=1}^{n} y_i,$$  

$$\tilde{\beta}_0 \sum_{i=1}^{n} x_i + \tilde{\beta}_1 \sum_{i=1}^{n} x_i^2 - \frac{\sum_{i=1}^{n} x_i^2}{2} = \sum_{i=1}^{n} y_ix_i.$$
4 Abstract and Applied Analysis

The study includes the analysis of integers $Z$ in accordance with time scale derivative definition. Standard definition is as follows [30]:

$$\hat{\beta}_0 Z_g = \left( -n \sum_{i=1}^{n} x_i^2 + \sum_{i=1}^{n} x_i \sum_{i=1}^{n} x_i^2 + 2 \sum_{i=1}^{n} x_i \sum_{i=1}^{n} y_i x_i \right)$$

$$\times \left( \left( -n \sum_{i=1}^{n} x_i^2 + \left( \sum_{i=1}^{n} x_i \right)^2 \right) / 2 \right)^{-1},$$

$$\hat{\beta}_1 Z_g = \left( -n \sum_{i=1}^{n} x_i^2 + 2n \sum_{i=1}^{n} y_i x_i + n \sum_{i=1}^{n} x_i \right)$$

$$\times \left( \left( -n \sum_{i=1}^{n} x_i^2 + \left( \sum_{i=1}^{n} x_i \right)^2 \right) / 2 \right)^{-1}. \tag{18}$$

4.2. Graphs with Data 10-20-30-40-50 of Normal Situation. Forward and Backward Jump Operator. Respective illustrations of simple linear regression equations obtained from samples of 10, 20, 30, 40, and 50 data for normal situation forward and backward operators are shown in Figure 2.

There is a relationship between sample size and sum of vertical distances between regression line and observation values $Y_i$ for sample sizes of $n = 10, 20, 30, 40, and 50$ provided in Table 1.

Minimum test calculated according to time scale derivative definition for forward and backward jump operators as is follows:

$$L = \sum_{i=1}^{n} x_i^2 - \left( \sum_{i=1}^{n} x_i \right)^2$$

$$= \frac{\sum_{i=1}^{n} (x_i - \bar{x})^2}{n}. \tag{21}$$

Minimum test calculated according to time scale derivative definition for forward and backward jump operators is as follows:

$$\frac{\partial^2 \hat{Q}_{ab}}{\partial a a} = \frac{\partial^2 \hat{Q}_{ab}}{\partial b b} = \frac{\partial^2 \hat{Q}_{ab}}{\partial a b} = \frac{\partial^2 \hat{Q}_{ab}}{\partial a b} = \sum_{i=1}^{n} x_i, \quad \sum_{i=1}^{n} x_i, \quad \sum_{i=1}^{n} x_i, \quad \sum_{i=1}^{n} x_i.$$ 

Since $L > 0$ and $Q_{aa} > 0$ always, $Q(k, m)$ always has a minimum value.

5. Results

In statistics, least squares method is used in accordance with the known derivative definition when parameters of regression equation are obtained. In the study, time scale derivative definition is applied to the least squares method. In this regard, (9) simple linear regression model is considered and both $\hat{\beta}_0$ and $\hat{\beta}_1$, estimators of $\beta_0$ and $\beta_1$ coefficients, are obtained in accordance with forward and backward jump operators. Different $\hat{\beta}_0$ and $\hat{\beta}_1$ parameter values are obtained, originating from forward and backward jump operators related to the $\hat{\beta}_0 = \hat{\beta}_1 x$ simple linear regression equation. In cases when observation values are discrete, forward jump operator equation $\sigma(t) = t + 1$ and backward jump operator equation $\rho(t) = t - 1$ are taken [31].

The study includes the analysis of integers $Z$ in accordance with time scale derivative definition. Standard
approach in regression analysis is to minimize the sum of squared (vertical) deviations between actual and estimated values. Here, the point which should be considered is that, since in least squares method, sum of squared vertical deviations is of interest, analysis would also operate accordingly. The issue of applying first and second derivatives should also be taken into consideration since the aim is to minimize the sum of squared vertical deviations. Since $L > 0$ and $Q_{a_a} > 0$ always, $Q(k, m)$ always has a minimum value.

Least square method yields results such that sum of vertical deviations is minimum. When least squares method is used according to time scale derivative definition, a relationship emerges between sample size and sum of vertical distances between regression line and observation values $Y_i$. This is derived from the sum of vertical distances between regression lines equal to half of sample size and observation values $Y_i$. To minimize the sum of vertical distances, different $\tilde{\beta}_0$ and $\tilde{\beta}_1$ parameter values resulting from forward and backward jump operators for simple linear regression equation $\tilde{y} = \tilde{\beta}_0 + \tilde{\beta}_1 x$ have been of interest. An alternative solution is to create a regression equation in time scale. As a conclusion, time scale derivative definition is applied to the study with integers $Z$ and suggested solutions are proposed for the results obtained.

### 6. Discussion and Possible Future Studies

This study is only introducing a very basic derivative concept from the time scale and applying for obtaining the regression parameters. An extension of this study would be determining the integer $Z$ apart from the value 1. This would be useful especially when the actual assumptions of linear regression model have been violated and need a robust estimation of linear regression line. Perhaps it is hard to determine an optimum of $Z$ analytically. We would suggest that the study should be performed for generated data containing outliers that is replicated at least 1000 times.

It is also possible to extend the number of regressors from a single explanatory variable to multiple ones in the linear regression model and estimate the parameters using time scale of both forward and backward jump operators. Analytically speaking, it will not be easy to estimate the parameters in a simple form of equation using time scale. In fact we would be dealing with very complicated either formulas or matrices. However it may be worth extending the study to a multiple linear regression model.

In the meantime taking $Z$ to be 1 results with the sum of vertical distances between regression lines equal to half of sample size (See Table 1 and Figure 2). The $Z$ value in both forward and backward jump operators should be determined in a way that the estimated regression line from both forward
