1. Introduction

Nuclear reprocessing is the process of chemically treating spent nuclear fuel to recover plutonium (Pu) and uranium (U). The aqueous process, PUREX, has conventionally been used for this purpose. However, pyroprocessing has recently emerged as one of the key technologies that can reduce nuclear waste while improving the efficiency of resource use in the nuclear fuel cycle. This is because, among other advantages over PUREX, pyroprocessing is less proliferative as it does not enable the separation of Pu from other impurities [1]. Pyroprocessing is a process that starts with the head-end process, followed by electrolytic reduction, electorefining, electrowinning, and salt purification [1–3].

The head-end process includes chopping, mechanical or oxidative decladding, and high-temperature voloxidation as unit processes. During the head-end process, uranium and transuranic (TRU) elements are recovered from spent fuel, while fission products such as Kr, Xe, H-3, C-14, Cs, and I are removed [4–6]. Another important goal of the head-end process is the fabrication of a proper feed material for the subsequent electrolytic reduction process. The feed material can take on different physical forms depending on the decladding method used: mechanical decladding results in crushed particles, whereas oxidative decladding results in porous pellets or granules. Compared to mechanical decladding, oxidative decladding results in a high recovery rate of the fuel material from rod-cuts [3]. However, during the oxidative decladding process, uranium oxide undergoes a change in phase from a UO\(_2\) pellet to a U\(_3\)O\(_8\) powder.

In this viewpoint, the UO\(_2\) porous pellet form, which can be prepared from the U\(_3\)O\(_8\) powder via ceramic processing, has attracted much interest as a promising feed form for the following electrolytic reduction [6–9]. The fabrication of a UO\(_2\) porous pellet involves pelletizing and sintering of U\(_3\)O\(_8\) pellets at high temperature under a H\(_2\)-containing atmosphere [6]. In this regard, there have been many studies that have investigated the reduction behaviors and microstructural variations of U\(_3\)O\(_8\) under reducing atmosphere [10–15]. However, the majority of such investigations have been carried out on a lab scale. Therefore, in order to achieve engineering-scale production (50 kg-U/batch), for example, at the PRIDE facility [9], it is necessary to determine if the fabrication process and the corresponding equipment need to be modified to suit mass production.
In the present experiment, based on the literature and conventional ceramic processing, a fabrication process was adapted to meet the needs of the fabrication scale in PRIDE facility: oxidation, mixing, pelletizing, and sintering. Towards this end, the fabrication equipment was newly designed and improved by introducing new structures. In addition, the relationship between the green density and sintered density under compaction pressure was investigated in the course of mass production. From a practical aspect, the results of this investigation can be employed to the mass production of UO₂ porous pellets, which can be used as a feed material for the subsequent electrolytic reduction process.

2. Materials and Methods

2.1. Fabrication of Porous Pellets. Similar to conventional ceramic processing, the fabrication of UO₂ porous pellets in the PRIDE facility involves four sequential processes: oxidation, mixing, pelletizing, and sintering. The fabrication process of the porous pellets and the chemical/physical form of the produced uranium oxides after each process are summarized in Table 1. Considering the purpose of the PRIDE facility, the fabrication equipment was designed to accommodate a capacity of 50 kg-U/batch; a schematic drawing of this equipment is shown in Figure 1. The porous UO₂ pellets were fabricated in the PRIDE facility as follows: UO₂ pellets with a diameter of 8.05 mm, a height of 10.08 mm, and a weight of 5.20 g were prepared as the starting material. The microstructures and a weight of 5.20g were prepared as the starting material. The geometrical density of UO₂ pellets was about 92.47% on average, much higher than the theoretical density of UO₂, 10.96 g/cm³. The UO₂ pellets were oxidized to U₃O₈ powder at 480°C for 16 h under a 75% O₂ - Ar atmosphere in a rotating drum furnace, which was equipped with a double chamber: an inner chamber made of INCONEL 600 and an outer chamber of SUS 304 stainless steel. A schematic drawing and a photograph of the rotating drum furnace are shown in Figure 1(a). On the inside wall of the inner chamber, a spiral screw structure is formed to allow transport of the UO₂ feed pellets and/or produced U₃O₈ powders back and forth by rotating the chambers. After complete oxidation of the UO₂ pellets, the oxidized U₃O₈ powder was recovered by reverse rotation of the chambers. The recovered U₃O₈ powder was mixed with 2 wt% of acravax (ethylene bis stearamide (EBS), C₃₆H₇₀O₂N₂, CAS #: 110-30-5) by using a tubular mixer for 30 min. Acravax is a well-known lubricant used to minimize die wall friction during the subsequent pelletizing process. The powder mixture containing EBS was then pressed into a pellet shape using the rotary press machine shown in Figure 1(b). A schematic drawing of the driving part of the rotary press shows 13 sets of die and punches (Figure 1(b)). In a single rotation cycle, U₃O₈ powder is injected into the hole of the die, followed by compaction of the filled powder in the die by the upper and lower punches and ejection of the pelletized U₃O₈; this cycle can be repeated continuously. The hole of the die used in this experiment was designed to be 6.6 mm wide, and the rotation speed of the rotary press was optimized to be 5 rpm during the pelletizing process. The green pellets obtained after pressing were sintered and reduced in a vertical-type sintering furnace that helped to minimize the temperature gradient throughout the heating zone. The heating elements penetrating the ceiling surface of the furnace chamber allow the samples to be completely surrounded by the heating element. The green pellets were put into five zirconia crucibles, which can contain ~13 kg of U₃O₈ pellets, and then sintered at 1350°C for 12 h under 4% H₂-Ar atmosphere.

2.2. Characterization of Porous Pellets. The microstructures of the U₃O₈ powders and UO₂ pellets were observed by scanning electron microscopy (SEM, Philips XL-30, Netherlands) after polishing using diamond paste. The pore sizes and size distributions were measured from the SEM images using the image processing software, Matrox Inspector 2.1 (Matrox Inc. Canada). The crystal structure of the fabricated UO₂ pellets was examined using X-Ray Diffraction (XRD, Rigaku MiniFlex, Japan). The XRD experiments were performed over the 2θ range of 20–80° and at a scan speed of 6°/min and a step size of 0.01°. The pellets were crushed into powder form in an agate mortar and pestle prior to the measurements.

3. Results and Discussion

Figure 2 shows the variations in the temperature and O₂ concentration during the oxidation process of UO₂ to U₃O₈ in a rotating drum furnace (Figure 2(a)) and macro/microscopic images of the resultant oxidized U₃O₈ powder (Figure 2(b)). The oxidation temperature was determined based on a previous report on the oxidation of UO₂ to U₃O₈ [16]. This was done taking into account the temperature difference measured during the preliminary test between the two different positions of the rotating drum furnace: temperature of heating element (Tᵢₑₜ) and inside chamber (Tᵢₑᵢ); through the heat treatment at 470–480°C for 16 h, fine U₃O₈ powders were produced without significant agglomerates, as shown in Figure 2(b), indicating homogeneous oxidation of UO₂ into U₃O₈.

⁴Ethylene bis stearamide, (CH₃NHC(O)C₆H₅)₂.
During the oxidation, the phase change is accompanied by volumetric expansion (~23.6%) due to the difference in density between the two phases: 10.96 g/cm$^3$ for UO$_2$ and 8.37 g/cm$^3$ for U$_3$O$_8$ [13]. The U$_3$O$_8$ powder particles, therefore, become popcorn shaped. In our experiment as well, the U$_3$O$_8$ powder particles were popcorn shaped, with an average particle size of 4.63 μm, as shown in Figure 2(b) [17, 18]. Both fine particle size and uniform phase of the produced U$_3$O$_8$ powder are conditions necessary for securing good compactability during the following pelletizing process. Before the pelletizing process, 0.2 wt% of acrawax was added to the U$_3$O$_8$ powders. Acrawax is a well-known lubricant material in powder metallurgy, and it reduces the friction between the die and the wall while improving the mechanical strength of the green pellet [19]. After addition of the acrawax, the powders were mixed using a tubular mixer for 30 min to improve the uniformity of the powders.

The mixed U$_3$O$_8$ powders were then compacted into pellets using a rotary press, as shown in Figure 2(b). The rotary press exhibited excellent production yield: 3,500 pellets per hour (7 kg-U/h). The rough shape of the U$_3$O$_8$ powder indicates that it has poor flowability, which leads to the failure of uniform die filling during the pelletizing process. To improve the flowability, in this experiment, a mechanical feeder was installed. Figure 3(a) shows a schematic of the mechanical feeder attached at the feeding part of the rotary press. It consists of three impellers and a powder scraper, which allow a constant amount of U$_3$O$_8$ powders to be filled in the rotating dies. With the rotary press machine, around 30 kg of U$_3$O$_8$ powders were compressed into green pellets, as shown in Figure 3(b).

With an aim of optimizing the processing parameters in the pelletizing experiment, the effect of compaction pressure on the density of green pellets was examined. The compaction...

pressure could be controlled by regulating the amount of U\textsubscript{3}O\textsubscript{8} powder filled into die hole and the pressing depth of upper punch. In this case, the compaction pressure ranged from approximately 100 to 200 MPa. The density of pellets increased linearly with the compaction pressure in the range of 60.33 to 68.14% TD, as listed in Table 2. The geometrical information and green density values for pelletization under different pressures are also summarized in Table 2. The pellets have similar size and weight, with little standard deviation in the values, thus indicating that a uniform amount of powders was filled and uniform force was applied during the pelletizing process using a rotary press machine. Figure 4 shows photographs of the green pellets pressed under different compaction pressure values. It is evident that the surface of the pellets becomes smoother with increasing compaction pressure.

To ensure that the U\textsubscript{3}O\textsubscript{8} green pellets are suitable as feed for electrolytic reduction, they must be sintered and reduced to UO\textsubscript{2} phase by heat treatment in the furnace. As shown in Figure 1(c), a vertical-type furnace was constructed for heat treatment of the green pellets (50 kg/batch). A vertical-type furnace was used in order to minimize the temperature gradient throughout the heating zone. The sample loaded at the center of the furnace was surrounded by the heating element. To secure mechanical stability up to high temperatures, the green pellets were placed in zirconia crucible that was 320 mm in diameter and 10 mm thick. Each crucible contained ~13 kg of U\textsubscript{3}O\textsubscript{8} pellets and could be stacked tightly on another crucible.

Figure 5 shows the programmed and measured temperature variations during sintering of the U\textsubscript{3}O\textsubscript{8} green pellets. The sintering was conducted at 1350°C for 12 h under a reducing atmosphere using a gas containing hydrogen (4% H\textsubscript{2}-Ar balanced). The thermal history includes dewaxing treatment at 700°C for 1 h to remove the added acrawax. The retarded heating and cooling rate could be attributed to

...the thick refractory ceramics coated inside the heating zone. Figure 5(b) shows the sintered UO₂ pellets with a scale of 30 kg-U/batch. Among the produced pellets, delamination cracks are observed at the end of some pellets, as shown in the inset photograph. The dashed circles in Figure 5(b) show the pellets that were crushed owing to the delamination cracks. The delamination crack is known to result from severe friction between the die and the wall during the pelletizing process [20]. When cracks are formed in the pellets, dust particles (<45 μm), which escape the cathode basket and infiltrate into the molten salt in the electrolytic reduction process, can be formed. The crack formation can be avoided by further optimizing the processing conditions, such as the amount of acrassaw, mixing time, and compaction pressure.

Figure 6 shows the XRD patterns of the sintered pellets extracted from different crucibles: top and bottom floor. All patterns are similar to that of the UO₂ phase, without any second phase. This indicates that all of the sintered pellets have the UO₂ phase, irrespective of their position in the furnace during the sintering. It also implies that the reduction...
of $\text{U}_3\text{O}_8$ to $\text{UO}_2$ was completed during the previous sintering process.

Figure 7 shows SEM micrographs of different positions in a pellet: inside and surface. The pore structures at the center/surface of the porous pellet were clearly observed after mechanical polishing but with no etching. Except a slight difference in the size of the pores and their connectivity, both from the inside and from the surface, a porous microstructure with interconnected micropores is clearly seen in the SEM micrographs. Compared to the pores on the surface, the pores inside the pellets were larger and more interconnected. The average pore size inside and on the surface of the pellets was 5.25 and 3.65 $\mu$m, respectively. This could be attributed to the preceding densification of the surface region, resulting in the escape of gas trapped in the pores deep inside the pellet.

Figure 8 shows the relationship between the green density of the $\text{U}_3\text{O}_8$ pellets and the sintered density of the $\text{UO}_2$ pellets with respect to the compaction pressure. In the following electrolytic reduction process, the density of a porous pellet is one of the major factors determining the reduction efficiency [20]. Generally, the sintered density of $\text{UO}_2$ pellets strongly depends on the green density of $\text{U}_3\text{O}_8$ pellets, which is determined by the compaction pressure in the pelletizing process. Therefore, to fabricate porous $\text{UO}_2$ sintered pellets within a suitable density range, the relationship between the compaction pressure, green density of $\text{U}_3\text{O}_8$ pellets, and sintered density of $\text{UO}_2$ pellets should be clarified. In this experiment, the following linear relationship was obtained in the compaction pressure range from 106 to 206 MPa:

$$\text{SD (\%)} = 0.35 \text{GD (\%)} + 39.87 \text{\%},$$  \hspace{1cm} (1)

where SD and GD are the percentages of sintered density and green density, respectively. This provides technical data for the fabrication of $\text{UO}_2$ porous pellets in large batches and can help in ensuring the quality assurance and quality control (QA/QC) of the porous pellets.

4. Conclusions

UO₂ porous pellets, which are promising as a feed material for the electrolytic reduction process in pyroprocessing, were fabricated in the PRIDE facility at an engineering scale. The fabrication processing was based on conventional ceramic processing, which consists of oxidizing, pelletizing, and sintering. To meet the demand for scaling up, three kinds of fabrication equipment were constructed, and the drawbacks in scaling up were addressed at the stage of design and fabrication. A screw structure in the rotating drum furnace helps to convey a large amount of powders/pellets by rotating the chambers in the oxidation process, a mechanical feeder improves the flowability of the U₃O₈ powders into the hole of dies during the pelletizing process, and a vertically penetrating heating element structure reduces the temperature gradient throughout the large space during the sintering process. In addition, this paper clarifies the relationship between green density, sintered density, and the compaction pressure in terms of the optimization of processing parameters as a practical aspect of the fabrication of UO₂ porous pellets.
