Dysregulation of cytokines is among the main abnormalities in Systemic Lupus Erythematosus (SLE). However, although, estrogens, which are known to be involved in lupus disease, influence cytokine production, the underlying molecular mechanisms remain poorly defined. Recent evidence demonstrates the presence of estrogen receptor in various cell types of the immune system, while divergent effects of estrogens on the cytokine regulation are thought to be implicated. In this paper, we provide an overview of the current knowledge as to how estrogen-induced modulation of cytokine production in SLE is mediated by the estrogen receptor while simultaneously clarifying various aspects of estrogen receptor signaling in this disease. The estrogen receptor subtypes, their structure, and the mode of action of estrogens by gene activation and via extranuclear effects are briefly presented. Results regarding the possible correlation between estrogen receptor gene polymorphisms and quantitative changes in the receptor protein to SLE pathology and cytokine production are reviewed.

1. Introduction

Systemic lupus erythematosus (SLE) is a chronic autoimmune disease of unknown origin that affects several organ systems; diverse immunological abnormalities that are associated with this disease have been recognized both in human and in animal models with the most consistent being: (1) loss of B cell tolerance, (2) abnormal interactions between T and B cell signaling, (3) T, B cell and monocyte hyperactivity, (4) production of a wide range of pathogenic autoantibodies resulting from polyclonal B cell activation, and (5) defective clearance of autoantigens and immune complexes [1–3].

The key components of the immune system such as B and T lymphocytes, dendritic/macrophage cells, monocytes and thymus are involved in the underlying mechanisms of SLE, while an imbalance between Th-1 and Th-2 cytokine production plays a key role in the induction and development of the disease [4, 5]. In particular, a switch from a type 1 (Th-1) to a type 2 (Th-2) T helper has been demonstrated where serum levels of Th-2 cytokines, such as interleukin IL-4, IL-6, and IL-10, are elevated, while there is an observed

decrease in production of Th-1 cytokines, including IL-2 and interferon IFN- γ [6, 7]. Among these cytokines, IL-10 seems to play a central role in the pathogenesis of SLE as well as in disease flare induction [8–10], while IL-6 has been identified as being a potent contributor to the differentiation of Th-0 to Th-2 cells [11], its production increasing in patients with active disease [12]. Moreover, the elevation of TNF- α in the serum of SLE patients has been suggested as playing a role in the pathogenesis of the disease [13–15]. It is therefore apparent that soluble mediators of immune responses such as cytokines remain prime candidates for the pathogenic factors responsible for this systemic disease.

Although SLE still remains of unknown origin, a strong genetic predisposition has been recognized, this often being accompanied by environmental and hormonal factors that contribute to the expression of the disease. Among the above risk factors, female gender is considered to be the greatest [16]. The observed high female prevalence is most marked after puberty: while the pre-puberty female to male ratio is 3 : 1, this increases to 10 : 1 during the childbearing years and decreases again to 8 : 1 after menopause.

Although estrogens have been proposed as obvious candidates to explain this sexual dimorphism [17], measurement of plasma estradiol levels did not reveal significant differences between normal women and women with SLE; nevertheless, abnormal levels of estrogenic metabolites have been identified in the latter. These metabolites include 2-hydroxy- and 16-hydroxyestrone and their derivatives produced by the enzymatic oxidation of estrogen. Additionally, pregnancy is frequently associated with flares of the disease in SLE patients [17]. Of note, pregnancy can disturb the balance in favor of the highly feminizing 16-hydroxy metabolites, thus predisposing to SLE, while exercise or consuming specific foods that inhibit the 16 α -hydroxylase can have opposite effects [18]. The alternative metabolic pathway—the 2-hydroxylation pathway—that leads to catechol estrogens has been found to be suppressed in SLE patients [19]. Administration of 17-beta estradiol (E_2) has also been observed to aggravate the disease in New Zealand brown/New Zealand white F1 female mice (a model of SLE) [20]. Interestingly, in lupus animal models, despite the elevated estrogen 2-hydroxylase activity, abnormal formation of 2-hydroxylated and 16 α -hydroxylated products have not been demonstrated [21]. Moreover, Klinefelter syndrome, a XXY genetic syndrome characterized by an abnormal estrogen/androgen pattern resembling the female pattern, is associated with higher prevalence of SLE among men [22]. Concerning the role of hormone replacement therapy and oral contraceptive pills in the risk of developing and/or exacerbation of SLE, this issue still remains controversial [23–28]. It is of interest to note that, while studies in women using oral contraceptives versus those not using oral contraceptives demonstrated no significantly increased risk of developing SLE, by contrast, hormone replacement therapy in postmenopausal women seems to increase this risk [29]. Oral contraceptive use was not associated with changes in the disease course in premenopausal women with SLE, at least in the nonactive phase, but hormone replacement therapy increased the risk of mild flares in postmenopausal patients [30].

2. Molecular Mechanisms of Estrogen Action

2.1. Nuclear Actions. Estrogens exert their effects by activating their intracellular receptors, the estrogen receptor alpha ($ER\alpha$) and beta ($ER\beta$) isoform, encoded by their respective genes *ESR1* and *ESR2* [31, 32]. These receptor proteins belong to the steroid receptor superfamily [33] and possess different sizes. Whereas $ER\alpha$ is comprised of 595 aminoacids, $ER\beta$ is comprised of 530 (today known as $ER\beta 1$ long). It should be pointed out that the original human $ER\beta$ clone encoded a protein of 485 aminoacids (today known as $ER\beta 1$ short). The $ER\beta 1$ long form is currently regarded as the full-length wild type $ER\beta$ [34]. Their aminoacid sequences are organized as follows: the ligand binding domain located in the carboxyterminal region of the molecules, necessary for ligand binding; the DNA-binding domain, responsible for binding to specific DNA sequences (the Estrogen Response Elements, EREs); and the transcriptional regulation domain (AF-1), which is highly immunoreactive and is located in the aminoterminal part of the molecules. $ER\alpha$ and $ER\beta$ exhibit

high homology in their DNA binding domain (96%), low homology (30%) in their AF-1 domain and partial homology (53%) in their ligand binding domain. Various $ER\alpha$ and $ER\beta$ isoforms and splicing variants ($hER\beta 1$ long, $hER\beta 1$ short, $hER\beta 2$, $hER\beta 4$, $hER\beta 5$, $hER\alpha 46$) have been described [34, 35]. $ER\alpha$ and $ER\beta$ mediate their effects via regulation of transcription of target genes, directly or indirectly, ligand-dependently or ligand-independently. Hereinafter, the term ER refers to both $ER\alpha$ and $ER\beta$ subtypes.

In the absence of hormone, ER is bound to a multiprotein complex, including heat shock proteins, which render the receptor inactive. The ligand binding (endogenous estrogens or exogenous synthetic estrogen analogs) induces a conformational change to the receptor, which results in the release of bound accessory proteins, and promotes homodimerization of ER subtypes ($ER\alpha$ and $ER\beta$ may homodimerize or heterodimerize) and high affinity binding to consensus EREs (AGGTCAnnnTGACCT) [36] located within the regulatory region of target genes [37].

The DNA bound receptors interact with many other coactivator proteins and negative coregulators/corepressors, resulting in the stabilization of a transcription preinitiation complex and the remodeling of chromatin and initiation of transcription by the basal transcriptional machinery and RNA polymerase [38–40]. Histone acetyltransferases (HATs) and histone deacetylases (HDACs) are key elements for the chromatin decompaction and initiation, such activities usually possessed by coactivator/corepressor protein complexes [39, 41, 42]. $ER\alpha$ and $ER\beta$ may regulate gene transcription not only via direct binding to their consensus EREs but also by their interaction with other transcription factors such as the AP-1 (via protein-protein interactions) and modulation of the binding of AP-1 to AP-1 binding sites onto DNA (AP-1 responsive elements), thus regulating AP-1 depending gene transcription [43]. $ER\alpha$ and $ER\beta$ respond differently to certain ligands in stimulating the ERE or AP-1 pathway [44]. For example, tamoxifen is a strong agonist of AP-1 dependent transcription in certain tissues (uterus, endometrium), promoting growth, while it acts as an antiestrogen via the classical EREs, in breast cancer tissue [45]. Similarly, estrogen receptor may interact with NF- κ B (via protein-protein interactions), resulting in modulation of the binding of NF- κ B to NF- κ B binding sites on the DNA (NF- κ B response elements), thus regulating NF- κ B dependent gene transcription. The estrogen receptor regulates NF- κ B mediated gene expression in a cell-type-specific manner and has important implications in inflammatory processes [46, 47].

Extracellular signals such as insulin, IGF-1, EGF, and TGF- β , phosphorylate $ER\alpha$ and $ER\beta$ (in the AF-1 region) via the mitogen activated protein kinases (MAPKs) in the absence of ligand, resulting in transactivation of the receptors and initiation of ERE-mediated gene expression [48]. Phosphorylation is a posttranslational modification of ERs on serine and tyrosine residues. Cellular enzymes such as kinases and phosphatases transfer a phosphate group from ATP onto target proteins or remove it, respectively. Estrogens as well as extracellular signals and regulators of the general cellular phosphorylation state (e.g. protein kinase A, protein kinase C, cyclin dependent kinases) [49] phosphorylate ERs,

thus affecting ER functions, positively or negatively, such as transcriptional activity, stability and nucleocytoplasmic shuttling. Estradiol, cell cycle regulators, the enzymes PKA, PKC, extracellular signals such as growth factors, cytokines and neurotransmitters phosphorylate human ER α at serine residues in the aminoterminal A/B domain (serine-104, -106, -118, -154, -167). Phosphorylation sites at serines in DBD, hinge region, and LBD (ser-236, -294, -305) have also been identified. Phosphorylation at ser-118 in human ER α is considered the consensus phosphorylation site for MAPKs and potentiates the interaction with coactivators, while phosphorylation of tyr-537 regulates ER α ligand binding. All together, the ER-mediated signaling cascade, that is, ligand binding, dimerization, DNA binding and interaction with cellular cofactors, seems to be regulated by phosphorylation of ER α (summarized in [50]). Studies on ER β phosphorylation suggest that ser-106 and ser-94 phosphorylation sites at the A/B domain modulate subnuclear mobility of the receptor, the ER β cellular levels, indicating thus that these phosphorylated serine residues generate signals to the ubiquitin proteasome pathway [51]. Phosphorylation at ser-106 and ser-124 also enhance the interaction with the coactivator SRC-1. Phosphorylation at ser-87 has been identified as a regulator of ER-dependent gene expression and growth of breast cancer cells [52]. Collectively, in the presence of diverse physiological signals other than their cognate ligand, the ERs may be activated, this accompanied by an increased phosphorylation state, a pathway which may be responsible for tissue-specific responses, especially in cases where the concentration of these extracellular signals (e.g., growth factors) is locally increased and estrogens are too low.

2.2. Extranuclear Actions

2.2.1. Plasma Membrane ER. Studies demonstrating that estrogens can cause effects too fast to be based on transcriptional events led to the identification of membrane estrogen receptors responsible for non-genomic responses. The estrogen receptor membrane form exists as a full-length ER, as an isoform, or as a distinct receptor [53–55]. Membrane forms for both ER α and ER β have been identified [56]. The membrane localization of ER has been shown to be mediated by the adaptor protein Shc and insulin-like growth factor I receptor [57], while interaction with caveolin-1 and palmitoylation occurring on a specific cysteine (C447) ER residue also plays an important role in this localization [57, 58].

Accumulated evidence strongly supports the importance of plasma membrane estrogen receptors in a variety of cells. GPR30, a G protein-coupled receptor (GPCR), binds E₂ with high affinity and generates rapid effects [58, 59], including stimulating Ca²⁺ mobilization from intracellular stores directly or via epidermal growth factor receptor (EGFR) transactivation, c-fos expression, adenylyl cyclase, and cAMP mediated signaling and ERK-1/2 in a variety of cell types [60].

Additional signal transduction pathways that are rapidly responsive to E₂ and originate from the membrane involve

the stimulation/inhibition (being dependent on the ER α or ER β subtype) of phosphoinositol-3hydroxy kinase (PI3K) and the family of MAP kinases, such as extracellular-regulated kinase (ERK), p38 β isoform, as well as the c-Jun N-terminal kinase (JNK) [61]. Indeed, E₂ has been shown to bind the transmembrane G-protein-coupled receptor homolog GPR30 and to activate p44/42 MAPK through transactivation of EGFR [62, 63]. Of note, the signaling from the membrane can also extend to other intracellular transcription factors such as AP-1 or NF- κ B, resulting in gene repression or activation.

The non-genomic actions of estrogens seem to be implicated in important functions such as cell growth, proliferation, differentiation and apoptosis of various cell types (endothelial, bone, neuronal cells, etc.). With regard to the immune system, there are studies confirming the presence of the membrane ER α receptor in peripheral blood mononuclear cells (PBMCs), with estradiol inducing NO release and calcium flux through binding to this receptor. It is of interest that the presence of tamoxifen did not antagonize this effect [64]. Moreover, estradiol acting in human monocytes induced the rapid release of NO through membrane ER α and/or ER β [64]. Benten et al. [65] confirmed the existence of membrane ER in T-cells; according to their study, binding of estradiol to membrane ER resulted in release of NO, an effect that was not abolished by the presence of tamoxifen.

2.2.2. Mitochondrial ER. Accumulating evidence has demonstrated that estrogens exert substantial effects on mitochondrial function, some of these effects being the following: (a) estrogens are potent stabilizers of ATP production during oxidative stress, while under basal conditions they show little effect on mitochondrial ATP production; (b) estrogens prevent Ca⁺⁺ influx into mitochondria under high excitotoxic stimulation; (c) estrogens protect mitochondria by preventing mitochondrial membrane potential collapse [66]. More importantly, E₂—regulates the expression of mtDNA-encoded respiratory chain subunits such as cytochrome oxidase subunits I, II, III in various cell types/tissue [67–69].

Several laboratories have reported the localization of ER α and ER β in mitochondria in various target cells and tissues by a variety of techniques such as immunohistochemistry, immunocytochemistry, and immunoblots using a wide range of antibodies. A number of studies have demonstrated the presence of ER α in mitochondria of female rat cerebral blood vessels, MCF-7 cells, HepG2 cells, and the 2C12 murine skeletal muscle cell line. Accumulating evidence supports the presence of ER β in the mitochondria in rabbit uterus and ovary, in MCF-7 cells, in endothelial cells, in primary neurons, primary cardiomyocytes, murine hippocampus cell lines and human heart cells, in human lens epithelial cells, human liver cancer HepG2 cells, osteosarcoma SaOS-2, sperm, and periodontal ligament cells [66, 70]. The localization of ER β in mitochondria has also been verified by proteomics. It should be noted that the wild type human ER β (known as ER β 1), and not the isoforms ER β 2 to ER β 5, is preferentially localized in the mitochondria [66, 70].

It is noteworthy that sequences showing partial similarity to ERE consensus sequence have been detected in the D-Loop

region, the major regulatory region of the mitochondrial genome [71, 72]. Several lines of evidence have demonstrated that ER α and ER β exhibit specific binding to these mtEREs [73], while the mitochondrial ER β in immortalized human breast epithelial cells (contain ER β only) has been directly associated with E2-induced expression of mtDNA-encoded respiration chain subunits (COXI, COXII of complex IV and ND1 of complex I) [74]. Collectively, the above data support the hypothesis that the mitochondrial genome may be a primary site of action of estrogens [71].

It is important to mention that an elevation of the mitochondrial transmembrane potential and ATP depletion has been observed in circulating lymphocytes of patients with SLE [75, 76]. Moreover, lupus T cells overexpress genes involved in mitochondrial electron transport [77], whereas a borderline association at nt4917 of the ND2 gene (complex I) and a significant association of the variant at nt9055 in the ATP6 or F0F1-ATPase gene (complex V) have been demonstrated in SLE patients [78]. The above data imply that the estrogen-mitochondria crosstalk may be of importance in the pathophysiology of SLE disease.

3. Estrogen Signaling and the Regulation of Cytokines in Immune Cells

Given the central role of estrogens in stimulating SLE disease and because cytokines are substantially involved in the pathogenesis of SLE, we herein provide evidence elucidating the molecular basis of the interplay between estrogen and cytokines in immune cells/organs known to be of crucial importance in the control of the autoimmune response. Because estrogens mediate their effects via estrogen receptors (nuclear isoforms and/or membrane receptor), studies have focused on the detection of the above receptors in the immune cells (B cell, T cells, dendritic/macrophages, monocytes) as well as in the immune organs (thymus) and their possible role in autoimmunity [79].

The thymus is an immune organ of prime importance since it is well known that CD4 $^{+}$ and CD8 $^{+}$ T cell development is a result of a complex process, starting with the migration of progenitors from bone marrow to the thymus and followed by positive and negative selection processes that are critical for both final maturation of T cells and prevention of autoreactivity [80]. The loss of thymus function, after ablation of a hyperplastic thymus has been shown to contribute to the development of SLE [81]. Moreover, the MRL/lpr strain (an SLE mouse model) develops early in life autoimmune diseases characterized by thymic atrophy [82]. Firstly, Stimson and Hunter [83] demonstrated estrogen receptors in the human thymocytes. Estrogen has been shown to lead to thymic atrophy through various mechanisms including, among others, modulation of the production of IL-7, an important regulator of T-lymphopoiesis [84]. It is of import to bear in mind, the presence of both ER α and ER β is required to exert this action, while in mice it has been demonstrated that ER α needs to be expressed in both the hematopoietic and stromal compartments of the thymus [85]; on the other hand, the

achievement of a full-sized thymus requires the presence of ER α in stromal but not in thymic cells [85].

Additionally to the T cell development, estrogen has been shown to exert important effects on T cell function through ERs which have been identified in both CD4 $^{+}$ and CD8 $^{+}$ T cells [86, 87] in a biphasic way. As already mentioned, that SLE is characterized by a shift from the balance between Th-1 and Th-2 subsets to Th-2 dominance. It is well known that low doses of estrogen promote enhanced Th-1 responses and increased cell-mediated immunity, while high doses of estrogen lead instead to increased Th-2 responses [88, 89]. Of note, the enhancement of Th-1 responses to low-dose estrogen required the presence of ER α , but not ER β [88]. The high estrogen levels that accompany pregnancy may account for the stronger humoral responses and possibly contribute to the flares that some SLE patients experience during pregnancy [90, 91]. This effect of estrogens seems to be achieved through direct alteration in the Th cytokine profile from a proinflammatory (IL-2, IFN- γ , TNF- α) to an anti-inflammatory direction (IL-4, IL-6, IL-10, TGF- β) [92]. Indeed, E $_2$ as well as estrone and estriol have been shown to stimulate IL-10 in human CD4 $^{+}$ cells [30, 93, 94], while their effect on antigen-stimulated secretion of TNF- α was biphasic, with enhancement at low concentrations and inhibition at high concentrations [93]. A stimulatory effect of estriol on IL-10 production, in contrast to the inhibitory effect on TNF- α , has also been revealed by Zang and coworkers [95]. Lambert et al. [96], in agreement with previous studies [97, 98], observed a significant E $_2$ induction of IL-4 secretion by purified CD4 $^{+}$ T cells, an effect mediated through ER α in a classical ligand-dependent manner. IL-2, another cytokine important for differentiation of T cell responses into Th-1 or Th-2 predominance, has been found to be suppressed by high concentrations of estradiol in activated peripheral blood T cells and CD4 $^{+}$ T cell lines [99].

A recent and highly interesting study by Xia et al. [100] showed that estrogen replacement therapy increased the IL-4 while decreasing IL-2 and IFN- γ secretion by T cells isolated from surgically induced menopausal women, an effect which seems to be mediated mainly through ER α . An ER α -mediated regulation of IL-2 and IFN- γ secretion is also exhibited in splenic T cells [101]. Other cytokines, like IL-12 which is a central stimulator of Th1 type cytokines [102], as well as IL-1, are also influenced by estrogen action in T cells, with divergent results [89, 103]. IL-17 is a novel cytokine derived from T cells which has been shown to play an important role in the Th-1/Th-2 balance [104] and has recently been implicated in the pathogenesis of SLE [105]. A recent study showed that estradiol reduces the production of IL-17 by upregulation of PD-1 (programmed death 1) expression within the Treg-cell compartment, an effect mediated through membrane ER [106, 107]. With respect to IL-6, most studies, albeit conducted in PBMC or whole blood cultures which include multiple cellular components, demonstrated an inhibitory effect of estrogen [108, 109].

Many studies have shown that estrogens regulate the cytokine gene expression in different cell types, via ER-mediated pathways, either directly through EREs or indirectly through interaction of ER with other transcription

factors including NF- κ B and AP-1 [43, 46]. EREs have been recognized in the promoter of IFN- γ and IL-10 genes [110, 111]. It is of note that NF- κ B response elements have also been found in the promoter of several cytokine genes like IL-6, IL-10, TNF- α , IL-1 β , IL-12, and IL-2 [112–114], while there are cytokines, that can be transcriptionally regulated through interaction of more than one transcription factor. Indeed, IL-2 is tightly controlled by several transcription factors that bind to the IL-2 promoter; these transcription enhancers include NFAT, NF- κ B, and AP-1, while there is evidence that all binding sites on the IL-2 promoter need to be occupied to ensure maximal transcription and production of IL-2 [114, 115]. Disturbances in the transcriptionally active proteins, including NFAT (nuclear factor of activated T cells), members of the AP-1 (c-Fos, c-Jun), and NF- κ B (c-rel, p50, p65) families, have been shown to modulate cytokine gene expression in activated T cells [112, 114, 116, 117]. Importantly, abnormal NF- κ B signaling characterized by decreased p65-RelA, increased c-rel and reduced NF- κ B DNA binding activity, associated with altered cytokine expression, has been recognized in T cells from SLE patients [118–121]. Similarly, disturbances in AP-1-signaling associated with alterations in c-fos protein expression and AP-1 DNA binding activity has also been demonstrated in T cells from SLE patients [122–124].

The question now arises: how the estrogen-estrogen receptor pathway cross-react with NF- κ B and/or AP-1 mediated signaling in lymphocytes to regulate cytokine gene expression? Mechanistic studies on the direct interaction between ER and NF- κ B/AP-1 in immune cells, which is presumed important in the control of estrogen-induced immune responses and cytokine expression, are only sparse. Zang et al. [95] were the first to reveal that estriol altered cytokine profile of human normal T cells through inhibition of I κ B α degradation [95]; interestingly, this effect was specific for NF- κ B and not for other transcription factors like AP-1, and was ER-mediated, since it was partially abolished in the presence of tamoxifen [118, 119]. However, a recent study has demonstrated that E₂, acting through ER β , could directly enhance NF- κ B activity in human T cells, suggesting that estrogen actions on NF- κ B activity may depend on ER and cell subtypes [125]. An enhanced transcriptional activity of nuclear NF- κ B p65 in macrophages from E₂-treated mice was also observed by Calippe et al. [126]; according to their results, this enhanced NF- κ B activation could be a consequence of the reduced PI3K activity, as a result of chronic exposure to estrogens, through direct or indirect mechanisms, a hypothesis, however, which remains to be elucidated.

Apart from T-cells, monocyte-derived dendritic cells are substantially involved in the pathogenesis in SLE. Dysfunctional dendritic cells in human SLE have been described. In studies describing dysfunctional dendritic cells in human SLE [127, 128], monocyte-derived dendritic cells from lupus patients displayed an abnormal phenotype characterized by accelerated differentiation, maturation, and secretion of proinflammatory cytokines, suggesting that they are in a preactivated state. Interesting effects of estrogens on the function as well as cytokine secretion by dendritic cells and

monocyte/macrophage have been demonstrated. Indeed, Douin-Echinard et al. confirmed that estrogens are required to generate optimal numbers of fully functional dendritic cells *in vitro*, while they induce secretion of IL-6 and IL-12; of note, these effects of E₂ were dependent on ER α and not ER β [129]. E₂ increased the B cell-stimulating IL-10 production by monocytes [130]. Moreover, estrogen can enhance release of IL-6, TNF- α and interleukin-1 (IL-1), from human activated monocytes and/or macrophages, through modulation of CD16 expression [131], although other pathways not involving CD16, whether or not ER-mediated, have previously been recognized [132–134]. At the same line, E₂ was found to increase TNF- α , IL-6, and TGF- β secretion by differentiated monocyte/macrophages [135]. It should be noted that in regard to TNF- α and IL-1 β , the existing literature is at present inconsistent, with E₂ either enhancing or inhibiting their secretion by macrophages/monocytes [30]. The divergent results concerning the estrogen effect on the expression of various cytokines would seem to be attributable to differences in the cell type, in concentrations of E₂, in type of experiment (*in vivo* or *in vitro*) as well as in duration (shortterm vs longterm) of E₂ exposure. In support of the latter, Calippe et al. [126] exhibited the fact that chronic *in vivo* E₂ administration promotes the expression of IL-1 β , IL-6, IL-12p40 by macrophages in response to TLR4 activation, whilst short-term *in vitro* exposure in E₂ decreased the expression of these inflammatory mediators.

All the above data strongly suggest that estrogens by acting via their receptors and their crosstalk with other transcription factors in immune cells and organs can modulate immunological parameters and processes that have been shown to be implicated in the pathogenesis of SLE.

4. Estrogen Signaling and the Regulation of Cytokines in SLE

Numerous disorders of the immune system and abnormalities in cytokine production have been described in patients with SLE. Although there is much indirect evidence for estrogen involvement in the lupus disease process, the direct role of estrogen/estrogen receptor-mediated pathways in regulating cytokine production in SLE patients has not as yet been clearly defined.

Pursuing the same line of research, Evans et al. [136] set out to investigate the effect of estrogen on spontaneous *in vitro* apoptosis of PBMCs and T cells from women with SLE. Although their data did not allow of any conclusion as to which cell type was predominantly affected by estrogen, nor whether this was a direct or an indirect effect, they nevertheless found that there was an estrogen-induced decrease in apoptosis combined with decreased TNF- α production in the presence of estrogens which could probably enable survival of autoimmune cells in SLE patients. In the same study, estrogen-induced production of other cytokines, like IFN- γ or IL-1 β , by PBMCs was not significantly different between normal and SLE cell cultures.

However, the first evidence for a molecular marker of estrogen action in lupus patients was provided by Rider et

al. [137], who suggested that estrogen-dependent changes in lupus T cell calcineurin could alter proinflammatory cytokine gene regulation and T-B cell interactions. Indeed, application of RNase protection assays revealed increased calcineurin expression in response to exogenous E_2 in cultured T cells from female lupus patients. Calcineurin is known to stimulate dephosphorylation of substrates such as nuclear factor of activated T cells (NFAT), resulting in transactivation of target genes, including IL-2 [138, 139]. NFAT is a transcription factor that forms a complex with Fos and Jun proteins in the nucleus of activated T cells. Dephosphorylation by calcineurin translocates NFAT from the cytoplasm to the nucleus, where it binds promoter sequences and activates IL-2 transcription [140, 141] as well as the CD40Ligand (CD40L) [142]. It should be mentioned that CD40L plays a central role in pathogenic humoral immune responses in SLE, providing contact-dependent Th signals for B cell production of class-switched antibodies [143–145].

Other transcriptional regulators that may be controlled indirectly by calcineurin include the NF- κ B (NF- κ B)/Rel proteins [146]. Rider et al., in seeking to delineate the molecular mechanisms involved in estrogen control of calcineurin [137], demonstrated that the estrogen-dependent increase in intracellular calcineurin mRNA and its activity is a direct effect, mediated through ER. The same research group established that 2-fluoro- E_2 exerted a significant increase in the amount of CD40L in peripheral blood T cells from SLE patients, which was blocked by ICI 182780 (thus implying a ER-mediated action) [147]. Extending their research ten years later, they demonstrated that by blocking estrogen receptors *in vivo* by an estrogen selective receptor downregulator (fulvestrant) in SLE premenopausal women, they reduced significantly the expression of calcineurin and CD40L (CD154) mRNA in peripheral T cells [148].

In 2001, another research group [149] examined whether changes in the cytokine milieu of SLE patients were associated with serum sex hormone levels. According to their results, SLE patients were characterized by higher levels of endogenous serum E_2 ; however, the observed abnormalities in the cytokine milieu did not correlate with the abnormal E_2 serum levels, suggesting that increased E_2 may induce cytokine abnormalities only early in the disease, without being implicated subsequently.

Given that SLE is considered to be a Th-2 cytokine-driven disease, while pregnancy is also a condition in which the cytokine environment is predominantly Th-2 polarized, with an enhancement of antibody-mediated immune responses, Doria et al. [150] decided to evaluate levels of selected cytokines in the humoral immune response during pregnancy in SLE patients. Notably, they found high serum levels of IL-10 in SLE patients either before or during pregnancy, thereby supporting the view that IL-10 overproduction in SLE is mainly constitutive rather than modulated by estradiol. By contrast, in the same study IL-6 serum levels in SLE women reflected the levels of E_2 during the three trimesters of pregnancy, thus suggesting its regulation by estrogen. Apart from the abovementioned studies focused on direct effects of E_2 on the cytokine

production in SLE, a very recent study [151] investigated in PBMC of SLE patients the interaction among cytokines and estradiol on the regulation of immune-response related molecules; interestingly, using DNA microarrays analysis, they failed to reveal any functional interaction between estradiol and IFN- α on the expression of interferon-inducible genes in SLE.

A sex-related expression of the disease, similar to that in man, is known to occur in several animal models of autoimmune diseases. In many genetic based murine models of lupus, including NZB/NZW F1 and MRL/lpr/lpr mice, the females also develop more severe disease and higher titers of autoantibodies at an earlier age [152, 153], while estrogen supplementation is associated with worsening disease and accelerated mortality. Supporting the direct implication of estrogen in the development and the course of experimental murine SLE, Sthoeger et al. [154] demonstrated therapeutic effects of tamoxifen (selective estrogen receptor modulator), while three years later the same group [155] suggested that these beneficial effects were associated with cytokine modulations; indeed, treatment with tamoxifen restored the levels of IL-2, IL-4, IFN- γ , TNF- α , and IL-1 to the normal levels observed in control mice, thus implying an estrogen receptor-mediated effect. High levels of serum estrogen have been associated with decreased IL-2 production in NZB/NZW mice [156], while E_2 treatment has been shown to result in increased serum TNF- α and IL-6 levels following LPS challenge in normal as well as in MRL/lpr/lpr mice; these changes were also blocked by tamoxifen [157].

5. ER and SLE

In 1986, Weusten et al. [158], following the detection of estrogen receptors in thymocytes and peripheral blood monocytes of SLE patients, for the first time proposed the possibility of an ER implication in the pathogenesis of SLE. At the same time, Kelly and Vertosick [159] suggested the hypothesis of a potential role of ER as an autoantigen in SLE; according to this hypothesis, the proposed target of autoimmune attack, i.e. the estrogen receptor normally resident in the nucleus, is physiologically more highly activated in women, while autoantigenicity of ER is enhanced in SLE patients owing to an abnormality of estrogen metabolism leading to metabolite-derivatives which favor ligand occupancy of the receptor.

Thereafter, numerous studies have been carried out specifically to identify quantitative and qualitative differences in estrogen receptor(s) related to SLE disease, to Th-1 and Th-2 cytokine expression as well as to clinical characteristics like age onset, clinical symptoms, and disease activity, all, however, with conflicting results. Indeed, Athreya et al. [160] as well as Suenaga et al. [161], studying PBMC and monocytes, did not find significant differences in the number of estrogen receptors, nor in their binding affinity, between SLE patients and normal women, while Feng [162] revealed differences related to the disease activity.

Since ER α splicing variants lacking specific functional domains have been found in human estrogen-responsive tissues and have been previously implicated in diseases

of estrogen-dependent tissues/cells, by affecting estrogen action, the expectation was that attention would be focused on the identification of possible differences in expression of such ER α splicing variants by immune cells and their correlation with SLE. Although Wilson et al. [163] suggested that the presence of ER splice variant with deletion of exon 5 (DER5) in PBMC was causally related to SLE, experimental results from our laboratory [164], in agreement with those provided by Suenaga et al. [87], have shown that patients affected by SLE expressed in their peripheral blood T cells, monocytes, and B-cell lines wild type ER α , DER5, and DER7 transcripts as did healthy individuals.

Since its first identification [32, 165], ER β has continued to be of particular interest as it is highly expressed in tissues related to the immune system, potentially implying that some of the immunomodulatory effects of estrogens might be mediated by this receptor form. Several studies have demonstrated that monocytes and lymphocytes express both ER α and ER β [50, 164, 166], while quantitative differences in the expression of ER α and ER β mRNA have been observed among cell populations such as T cells, B cells and monocytes as assessed by Real Time Quantitative PCR (RQ-PCR). Indeed, CD4⁺ T cells have been found to express relatively high levels of ER α mRNA compared with ER β mRNA, whereas B cells expressed high levels of ER β mRNA and low levels of ER α mRNA [50, 166]. Additionally, in the same study by Phiel et al. [166], CD8⁺ T cells and monocytes expressed comparably low levels of both ERs. Recently, proceeding in the same line of research, Xia et al. found that both ER α and ER β were expressed on T cells of surgically induced menopausal women, with the expression of ER α being higher than that of ER β [100]. At mRNA level, both ER α and ER β are expressed by PBMC, as well as by T cells isolated from lupus patients [137, 164]. However, a recent study [167] conducted on PBMC of SLE patients has demonstrated increased expression of ER α mRNA and decreased expression of ER β mRNA compared with PBMC from normal controls. Interestingly, the highest expression of ER α was observed in CD4⁺ and CD8⁺ T cells from SLE patients, whereas ER mRNA expression by B cells from SLE patients was decreased compared with normal B cells; regarding ER β , a significant inverse correlation between ER β mRNA expression and the SLEDAI score was discerned. In contrast, Rider et al. [168] found that the expression of ER α or ER β , as estimated by immunoblotting, was independent of SLE disease activity, while both ER α and ER β agonists increased calcineurin and CD40L expression in SLE T cells but not in normal T cells. It is of interest to note that, although the amount of ER α appeared to be less in SLE T cells than in control T cells, this receptor subtype participated more than ER β in the sensitivity of SLE T cells to estrogen. These results, although in need of further clarification, are indicative of a possible stronger influence of estrogen on T cells, mediated mainly through ER α in SLE patients.

It must be mentioned here that mRNA expression is not always correlated with expression at the protein level or with the number of functional ERs simply because posttranscriptional modification of this receptor has been shown to occur; this could offer a possible explanation

for the conflicting results observed during the quantitative evaluation of ER α and ER β in immune cells [169].

Polymorphisms occur frequently throughout the human genome and in some cases are known to alter either the expression or the function of a gene product [170]. Several studies have demonstrated the presence of a variety of estrogen receptor polymorphisms and their association with various diseases, among them SLE. Results from our laboratory indicated that the estrogen receptor alpha codon 594 genotype may influence the development of SLE at a younger age, as well as a specific disease clinical pattern, while another two ER α polymorphisms in exon 1 (codon 10 and codon 87) were not associated with the disease [171]. Other studies have shown that PvuII and XbaI polymorphisms (intron 1 of ER α) were associated with a milder form of SLE characterized by skin manifestations, less organ damage as well as with early onset of the disease [172, 173]. In the same line, a previous study by Liu et al. [174] associated the PpXx genotype with a higher frequency of skin rashes and arthritis in SLE patients, while hematological abnormalities and hypertension were more severe in patients with ppXX, and renal vasculitis and interstitial injury in those with PpXX genotype. Moreover, the PpXx genotype of the ER gene was associated with the susceptibility of SLE in the male but not in the female. A very recent study conducted an interesting analysis of the relationship between estrogen receptor polymorphisms and the Th1 and Th2 cytokine expression in patients with SLE. According to their results, Pvu II and XbaI polymorphisms are associated with an alteration in the Th-1/Th-2 balance in favor of Th-2, increasing the susceptibility to SLE. The findings indicated that ER α gene polymorphisms could influence the expression of IL-10, IL-4, IL-2 and IFN- γ in SLE, with the Th-2 cell being predominant in patients with PpXx and PpXX genotypes [175]. Finally, another recent study determined the impact of estrogen receptor null genotypes on disease in NZM2410, and MRL/lpr mice, as a method to define the role of estrogen receptor signaling in lupus. Their data demonstrated a key role of ER α , but not ER β , in the development of lupus-like disease in female NZM and MRL/lpr mice [176].

6. Conclusion

SLE is characterized by numerous immune system disturbances including alterations in cytokine regulation. Estrogens are known modulators of immune system functions, influence cytokine production and are involved in the lupus disease process. Accumulating evidence on the molecular and cellular actions of estrogens via the estrogen receptor subtypes ER α and ER β adds to the depth of our understanding of estrogen-estrogen receptor mediated signaling. Both estrogen receptor proteins have been detected in immune cells, while increasing information points to their possible involvement in cytokine expression. However, in spite of the clinical significance of the estrogen-induced changes in cytokine production in SLE disease, many of the key elements in the underlying molecular mechanisms remain largely unknown. Existing data show an estrogen receptor-mediated effect in the production of cytokines and other cytokine

regulatory molecules (such as calcineurin and CD40L) in humans and animal models of SLE disease. A possible correlation of ER gene polymorphisms and of quantitative and qualitative changes in the receptor proteins to cytokine production and to disease aetiopathogenesis have also been reported. Clearly, further elucidation of ER signaling in SLE awaits characterization of the interactions of ER with the many other intracellular molecules and/or its interplay with other signaling pathways.

Recent evidence indicates a role of estrogens in mitochondrial function in immune cells along with cytokine regulation, while the existence of mitochondrial ER in human cells has been associated with stimulation of mitochondrial encoded enzymes. The above data, together with the recent findings that SLE patients are characterized by mitochondrial dysfunction, suggest that novel pathways of the estrogen-ER complex in mitochondria in immune cells may play a key role in SLE. The use of gene and/or protein expression profiling by microarray technology as well as the application of other molecular biology techniques in elucidating the underlying mechanisms will provide valuable information about the "signature" of the ER-regulated cytokine profile that are highly likely to be helpful in the design of future therapeutic strategies.
