CD8⁺ T cells are an essential component of an effective host immune response to tumors and viral infections. Genetic immunization is particularly suitable for inducing CTL responses, because the encoded proteins enter the MHC class I processing pathway through either transgene expression or cross-presentation. In order to compare the efficiency and persistence of immune response induced by genetic vaccines, BALB/c mice were immunized either twice intramuscularly with DNA plasmid expressing a codon-optimized HIV-1 gp120 Envelope sequence together with murine GM-CSF sequence or with a single immunization using an integrase defective lentiviral vector (IDLV) expressing the same proteins. Results strongly indicated that the schedule based on IDLV vaccine was more efficient in inducing specific immune response, as evaluated three months after the last immunization by IFN γ ELISPOT in both splenocytes and bone marrow- (BM-) derived cells, chromium release assay in splenocytes, and antibody detection in sera. In addition, IDLV immunization induced high frequency of polyfunctional CD8⁺ T cells able to simultaneously produce IFN γ , TNF α , and IL2.

1. Introduction

The importance of CD8⁺ T cells in viral clearance has been established in several viral models [1], including the nonhuman primate model of AIDS, in which depletion of CD8⁺ T cells resulted in the inability to clear infection [2, 3]. Several other evidences demonstrated the importance of the CD8⁺ T cell responses for controlling HIV infection. Indeed, slow AIDS disease progression is associated with functional CD8⁺ T cell responses, specific HLA class I alleles are associated with slower progression of disease in HIV-infected people, and CTL escape is a major force driving HIV evolution (reviewed in [4, 5]). Based on these findings, vaccines inducing strong and long-lived CD8⁺ T cells are highly desirable. Genetic immunization using plasmid DNA

or viral vectors is particularly suitable for inducing CTL responses, because the encoded protein enters the MHC class I processing pathway through either direct transgene expression or cross-presentation by resident antigen presenting cells (APCs). Among viral vectors, lentiviral vectors (LVs) have been shown to efficiently transduce non replicating cells in vitro as well as in vivo and to be able to elicit potent humoral and cellular responses (reviewed in [6]). LV-transduced human DCs are able to present antigenic peptides and prime transgene-specific T cells in vitro [7, 8]. It has been shown that LV-encoding HIV-1 polyepitopes induce broad CTL responses in mice [9], and we reported that a single intramuscular administration of HIV-based LV-expressing viral antigens elicits strong cell-mediated immune responses [10, 11]. Importantly, Beignon and colleagues

FIGURE 1: HIV-based transfer vectors plasmid used in this study. The internal CMV promoter drives the expression of the codon-optimized HIV_{JR-FL} gp120 Envelope protein and the murine GM-CSF (mGM-CSF). The packaging signal (Ψ), primer binding site (PBS), major splice donor (SD) and acceptor (SA) sites, bovine Growth Hormone polyadenylation signal (bGHpA), central polypurine tract (cPPT), internal ribosomal entry site from poliovirus (pIRES), and Woodchuck posttranscriptional regulatory element (WPRE) are indicated.

recently provided the first evidence that an LV-expressing simian immunodeficiency virus- (SIV-) Gag protein was able to induce control of viral replication in monkeys challenged with high dose of SIV [12]. However, safety concerns relative to the use of these vectors for delivery of therapeutic genes or for a vaccine include insertional mutagenesis and/or vector mobilization following viral infection. To minimize the risk of insertional mutagenesis, integrase defective lentiviral vectors (IDLV) have been engineered to present viral antigens in a similar but safer manner [13, 14]. Several reports have shown that HIV- or SIV-derived integrase defective viruses as well as IDLV are transcriptionally active although at lower levels than the integrated wild-type counterpart, while producing extrachromosomal forms of viral DNA (E-DNA) in the absence of noticeable amounts of integrated provirus [14, 15].

We have recently demonstrated that a single immunization with a nonintegrating lentiviral vector carrying a codon-optimized HIV-1 gp120 Envelope protein in mice results in a strong and sustained immune response characterized by the presence of anti-gp120 antibodies, effector-specific T cells and generation of a specific T cell memory, without integration of the vector into the host genome [16]. Importantly, several groups confirmed the use of IDLV as an effective vaccine delivery strategy [17–19], and we provided evidence that SIV-based IDLV can be constructed and used as well [20].

In this work we compared the ability to induce long-lasting CD8⁺ T cell response in mice upon immunization with DNA plasmid or IDLV expressing the HIV-1 gp120 Envelope protein. A detailed evaluation of CD8⁺ T cell immune response was performed at three months after the last immunization. Moreover, a comprehensive analysis of the quality of CD8⁺ T cell response induced by IDLV is reported.

2. Materials and Methods

2.1. Vectors Construction. A schematic depiction of the lentiviral transfer vector plasmids used in this study is shown in Figure 1. Details on vectors construction are

provided in [16]. Briefly, the HIV-based transfer vector plasmid pTY2-JRmZ encodes the HIV-1_{JR-FL} gp120 Envelope protein sequence (HIV-Env) and the murine granulocyte monocyte-colony stimulatory factor (mGM-CSF) from the internal CMV promoter; the HIV-based transfer control vector plasmid pTY2-EmptyZ encodes only the mGM-CSF from the sequence for the poliovirus internal ribosomal entry site (pIRES). The Integrase (IN) defective packaging plasmid pcHelp/IN-, obtained from Dr. J. Reiser (Louisiana State University Health Sciences Center, New Orleans, USA), is necessary for production of the vector particles and contains a D116N mutation in the IN genome, preventing the functions characteristic of the IN protein [16]; plasmid pMD G [21], obtained from Dr. D. Trono (University of Lausanne, Switzerland), produces the vesicular stomatitis virus envelope glycoprotein G (VSV G).

2.2. Production of Recombinant Vectors. The human epithelium kidney 293T cell line was maintained in Dulbecco's Modified Eagles medium (Euroclone, Life Sciences Division, Pero, Milan, Italy) supplemented with 10% fetal calf serum (Euroclone, Life Sciences Division) and 100 units/mL of penicillin-streptomycin-glutamine (Gibco Invitrogen, Paisley, UK). For production of recombinant IDLV expressing HIV-Env (IDLV-JRmZ), cells were transiently transfected using the calcium phosphate-based Profection Mammalian Transfection System (Promega Corporation, Madison, WI, USA) as previously described [16, 22] using a total of 24 μ g of plasmid DNA with a ratio of 4 : 3 : 1 (pTY2-JRmZ:pcHelp/IN-:pMD G), thus producing the IDLV-JRmZ vaccine preparation. For production of control recombinant IDLV (IDLV-Empty), the pTY2-EmptyZ plasmid was used in place of pTY2-JRmZ, thus producing the IDLV-Empty vaccine preparation. After 48 hours, culture supernatants were cleared from cellular debris and passed through a 0.45 μ m pore size filter (Millipore Corporation, Billerica, MA, USA). Filtered supernatants were concentrated by ultracentrifugation (Beckman Coulter, Inc., Fullerton, CA, USA) for 2 hours at 27 000 rpm on a 20% sucrose gradient (Sigma Chemicals, Co., St. Louis, MO, USA). Finally, the viral pellets were resuspended in 1 $\times$ PBS

and stored at -80°C for further analyses. Viral titres were normalised by the RT [23] and p24 ELISA assays (Innotest, Innogenetics, Belgium).

2.3. Mice Immunization. BALB/c mice were kept in accordance with the European Union guidelines and Italian legislation. All protocols were approved by the authors' Institutional Review Board. Four mice per group were intramuscularly immunized (i) twice with plasmid pTY2-JRmZ expressing HIV-Env and mGM-CSF (DNA-JRmZ), (ii) twice with plasmid pTY2-EmptyZ expressing only mGM-CSF (DNA-Empty); (iii) once with IDLV expressing HIV-Env and mGM-CSF (IDLV-JRmZ) and (iv) once with IDLV expressing only mGM-CSF (IDLV-Empty). Mice from DNA groups were immunized intramuscularly with DNA ($80\text{ }\mu\text{g}/\text{mouse}$) on day 0 and after 1 month were boosted with the same dose of DNA. Mice from IDLV groups received a single inoculum of 1×10^7 RT units of IDLV formulated in 0.2 mL of PBS. Naïve mice were added as further control. Three months after the immunization mice were sacrificed. At sacrifice mice were first bled orbitally under metaphane-induced anesthesia, and sera were collected and kept at -80°C . Single cell suspension from spleen was prepared by mechanical disruption and passage through cell streiners (BD Falcon). BM-derived cells were obtained from tibiae by syringe insertion into one end of the bone and flushing with RPMI medium.

2.4. IFN- γ ELISPOT Assay. The IFN- γ ELISPOT assay was performed on splenocytes and BM-derived cells by using reagents from Mabtech (Mabtech AB Gamla Värmdöv, Sweden) as described in [16]. The JR-9mer peptide containing the H-2^d restricted HIV-1 gp120 Envelope epitope (IGPGRAFYT) (UFPeptides s.r.l., Ferrara, Italy) and the H-2^d restricted GFP-9mer peptide (HYLSTQSAL) (UFPeptides s.r.l., Ferrara, Italy) were used at $5\text{ }\mu\text{g}/\text{ml}$ as specific and unrelated stimuli, respectively. Concanavalin A (SIGMA, Chemical Co. St. Louis, MO, USA) was used as a positive control. Specific samples (specific peptide-treated wells) were subtracted from the values obtained in the unrelated peptide-treated wells (background) and were scored positive when were present a minimum of 50 spots per 10^6 cells and a fold of 2 or higher compared to the unrelated peptide-treated samples.

2.5. Antibodies and Intracellular Staining (ICS). Splenocytes from single animals (four mice/group) were cultured with the specific JR-9mer ($5\text{ }\mu\text{g}/\text{mL}$) or the unrelated GFP-9mer ($5\text{ }\mu\text{g}/\text{mL}$) H-2^d-restricted peptides in the presence of anti-mouse CD28 mAb (clone 37.51) at $2\text{ }\mu\text{g}/\text{mL}$. PMA ($50\text{ ng}/\text{mL}$) in combination with Ionomycin ($2\text{ }\mu\text{g}/\text{mL}$) was used as positive control. After 1 hour from the stimulation, $10\text{ }\mu\text{g}/\text{ml}$ of Brefeldin A was added to the cultures as a protein transport inhibitor. After 6 hours of incubation, cells were stained with PercP anti-mouse CD8a, or the isotype-matched mAb. Then cells were permeabilized and stained with PE-labeled anti-mouse IL2, APC-labeled IFN γ , and PE-Cy7-labeled TNF α mAbs or their isotype-matched controls

in PBS-0.5% saponin and analyzed by flow cytometry. All monoclonal antibodies were from BD Pharmingen (San Diego, CA, USA), and all chemicals were from Sigma Chemicals, Co. (St. Louis, MO, USA). Acquisition and analysis were performed using FACSCanto and FACS Diva software (BD Biosciences, USA).

2.6. In Vitro Stimulation of Effector Cells and $^{51}\text{Chromium}$ Release Assay. Stimulator splenocytes from naïve BALB/c mice were pulsed for 1 hour with the Envelope-specific JR-9mer H-2^d-restricted peptide at $5\text{ }\mu\text{g}/\text{mL}$ in serum-free medium, irradiated with 3000 Rads on a ^{60}Co source, washed once, and then added to effector splenocytes derived from immunized mice, at an effector : stimulator ratio of 10 : 1. After 4 days of culture, effector cells were tested in $^{51}\text{Chromium}$ release assays for the analysis of antigen-specific T cells, as described in [16].

2.7. Antibody Detection. Specific antibody titres against HIV-gp120 Envelope protein were measured by ELISA as previously described [16]. Briefly, ninety-six flat-bottom well microplates (Nunc GmbH & Co. KG, Wiesbaden, Germany) were coated with $100\text{ ng}/\text{well}$ of HIV-1_{SF162} gp120 (NIH Repository Reagents, Bethesda, MD, USA) in carbonate buffer (Sigma Chemical Co. St. Louis, MO, USA). After overnight incubation at 4°C , wells were washed and mice sera were serially diluted and added to the plates. Goat anti mouse IgG peroxidase-conjugated secondary antibody (Sigma Chemical Co. St. Louis, MO, USA) was added to each well and incubated for an additional 90 min at 37°C . Antigen-bound antibodies were revealed by the addition of ABTS solution (Roche Diagnostic S.p.a, MI, Italy). Cut-off values were established for each plate and in each run and were based on the average serum samples plus 2 standard deviations (SD) from 4 naïve mice (Δ value). Serum samples with Δ values higher than the cut-off value were considered to be positive by ELISA for HIV-Env antibodies.

2.8. Statistical Analysis. Statistical analyses were performed by nonparametric Mann-Whitney U test. All P -values were two tailed and considered significant if less than .05. All analyses were performed using SPSS for Windows version 13.0 (SPSS Inc., Chicago Illinois US).

3. Results and Discussion

3.1. IDLV Is More Efficient than DNA in Inducing Antigen-Specific IFN γ Producing CD8⁺ T Cells in Splenocytes and BM-Derived Cells. The presence and the persistence of the immune response were evaluated at 90 days from the last immunization in mice (4 mice/group) inoculated twice with plasmid DNA (DNA-JRmZ) or once with IDLV (IDLV-JRmZ), both expressing codon-optimized HIV-1_{JR-FL} gp120 Envelope and murine GM-CSF. Control arms (4 mice/group) included mice inoculated twice with plasmid DNA (DNA-Empty) or once with IDLV (IDLV-Empty), both expressing only murine GM-CSF, as well as naïve mice. As determined

FIGURE 2: T cell responses measured on splenocytes (a) and BM-derived cells (b) at 90 days from immunizations. Results from one representative experiment out of three independent experiments are shown. IFN- γ ELISPOT was performed on cells stimulated overnight with either H-2^d restricted specific Envelope JR-9mer peptide or H-2^d restricted unrelated GFP-9mer peptide. IFN- γ producing T cells are expressed as SFC/10⁶ cells after background subtraction (see Section 2). The error bars indicate the standard deviation among four mice of the same group, and *P*-values are indicated for intergroup comparisons.

by IFN γ ELISPOT on ex vivo splenocytes, IDLV-JRmZ-immunized mice showed a high level of antigen specific IFN γ producing T cells, with spot forming cells (SFC)/10⁶ ranging from 473 to 960, with an average value of 662 (Figure 2(a)). The number of antigen-specific IFN γ producing T cells was lower in mice immunized twice with DNA-JRmZ (SFC/10⁶ cells ranging from 35 to 345, with an average value of 150) (Figure 2(a)). The difference between groups was statistically significant ($P < .01$).

Recently, it has been proposed that the bone marrow (BM) is a crucial organ for trafficking of mature T cells and contributes greatly to long-term cytotoxic memory as well as to homeostatic regulation of peripheral CD8 T cell numbers [24]. To evaluate if the vaccinations induced a memory response detectable three months after the last immunization in BM, IFN γ ELISPOT was performed on BM-derived cells. IDLV-JRmZ-treated mice showed detectable levels of antigen-specific IFN γ producing cells localized in BM (SFC/10⁶ cells ranged from 107 to 337, with an average value of 212) (Figure 2(b)). This is particularly striking in light of the fact that only 2%-3% of the cells derived from BM were CD8+. Conversely, antigen-specific IFN γ producing cells were not detected in BM of DNA-JRmZ-immunized mice

(Figure 2(b)). The difference between groups was statistically significant ($P < .05$).

Overall, these results indicate that a single injection of IDLV-JRmZ is more efficient than two immunizations with DNA-JRmZ in inducing antigen-specific IFN γ producing CD8+ T cells. In addition, the presence of immune response in spleen and BM at three months from the single immunization indicates that IDLV is able to induce a long-lasting immunity.

3.2. IDLV Immunization Induces Functional Cytotoxic T Lymphocytes (CTLs). To analyze the effective ability of antigen-specific CD8+ T cells induced by the vaccines in killing target cells, a chromium release assay was performed. This was deemed necessary since production of IFN γ by CD8+ T cells does not directly imply their ability to kill target cells, as it has been already demonstrated for instance in the case of HIV-infected patients, where the ability to produce cytokines was not associated with the cytolytic function [25].

The presence of CTL was investigated on splenocytes derived from immunized mice, stimulated in vitro with irradiated naïve splenocytes pulsed with the specific Envelope JR-9mer peptide. Specific lysis of target cells was evident in mice immunized once with IDLV-JRmZ (up to 30% of specific lysis at E : T ratio of 40 : 1), whereas splenocytes from mice immunized twice with DNA-JRmZ did not show CTL activity at any E : T ratio tested (Figure 3(a)). No specific responses were detected in the mice immunized with DNA-Empty, and IDLV-Empty and in naïve mice, used as negative controls (Figure 3(a)).

These data clearly indicated that only the immunization with IDLV-JRmZ was able to induce antigen-specific CD8+ T cells competent for both cytokine production and cytolytic effector function.

3.3. IDLV Immunization Induces Antigen-Specific Antibody Response. An efficient antibody response was not expected upon immunization with IDLV-JRmZ, due to the reported low protein expression from the non-integrated viral E-DNA [14]. Indeed, mice immunized with IDLV-JRmZ displayed low but detectable anti-Env IgG titers (geometric median titer 400) whereas mice immunized with DNA-JRmZ did not generate any antibody response (Figure 3(b)). Results were comparable to those obtained in a previous experiment using the same IDLV [16]. The presence of a specific antibody response in the case of IDLV is attractive, considering a possible prime-boost vaccine protocol, using IDLV as priming and the corresponding protein for boosting humoral response.

3.4. IDLV Immunization Induces Polyfunctional CD8+ T Cells. Several authors have recently confirmed the efficacy of IDLV vaccination in animal models [17–20, 26]. Due to its safety profile and immunization efficiency, there is, therefore, an increasing interest in the use of this vector for vaccine purposes in different disease models, including viral infections and tumors [27].

To further characterize the CD8+ T cell response, we carried out a more detailed analysis of the quality of immune

FIGURE 3: (a) Anti-Env specific CTL activity in mice immunized with IDLV-JRmZ, IDLV-Empty, DNA-JRmZ, and DNA-Empty or in naive mice (four mice/group). Results from one representative experiment out of three independent experiments are shown. ^{51}Cr -release assay was performed after 4 days in vitro culture, as described in Section 2. The percentage of specific lysis is shown at three different E : T ratios: 40 : 1, 20 : 1, and 10 : 1. (b) Anti-HIV-Env IgG antibodies measured by ELISA in sera of mice at 90 days after immunization. Sera samples from the immunized mice were analyzed separately. Line represents the geometric median value in the IDLV-JRmZ group.

response induced by IDLV immunization. In particular, an intracellular staining (ICS) for IFN γ , TNF α , and IL2 was performed in splenocytes of mice immunized with IDLV-JRmZ and DNA-JRmZ and control mice. As shown in Figure 4(a), CD8+ T splenocytes from both IDLV-JRmZ- and DNA-JRmZ-immunized animals produced all three cytokines, when cultured in vitro in the presence of the Envelope-specific peptide. Importantly, IDLV-JRmZ-immunized mice showed a statistically significant higher percentage of CD8+ T cells producing IFN γ , TNF α , or IL2 when compared to DNA-JRmZ-vaccinated mice ($P < .05$). Splenocytes from

naïve mice or from mice immunized with IDLV-Empty and DNA-Empty did not show any significant production of cytokines.

To evaluate the presence of polyfunctional antigen-specific CD8+ T cells, IFN γ producing CD8+ T cells were gated and evaluated for production of TNF α and IL2. In Figure 4(b) a representative analysis shows that the majority of the IFN γ -producing CD8+ T cells from the IDLV-JRmZ and DNA-JRmZ-immunized mice also produce TNF α and IL2 (86% and 75%, respectively). These results indicate that while both vaccinations qualitatively induced similar CD8+ T cell responses, immunization with IDLV induced a higher number of polyfunctional antigen-specific T cells.

It has been suggested that the presence of such polyfunctional cells correlates with a better prognosis in chronically infected patient with CMV and EBV and in long-term non progressor HIV-1-infected patients [28]. Therefore, the use of IDLV-based vaccines, capable of inducing high levels of polyfunctional CD8+ T cells, after a single immunization represents a very attractive and desirable vaccine strategy.

4. Conclusions

Usually, the immune response induced by DNA injection is weak. To circumvent this limitation in our study we used a single intramuscular injection of IDLV-delivered Envelope sequence in the mouse model which performed better than two immunizations with naked DNA plasmid delivering the same antigen. The mGM-CSF coding sequence was included in both immunization protocols in the effort to improve immune response. Nevertheless, two immunizations with DNA were not sufficient to induce an immune response comparable to that induced by a single immunization with IDLV expressing the same antigen. The difference in the ability to induce immune response could be partly explained by considering the advantage of the vector, in terms of uptake and stability in vivo, compared with naked DNA. The delivery of DNA through electroporation (EP) might overcome these limitations, even if safety-related issues of EP, in the case of administration of vaccines to humans, need to be better investigated [29]. However, the aim of our study was to provide evidence of the potency of IDLV as a vaccine and to characterize the CD8+ T cell response induced by this novel, safe, and promising vector for genetic immunization.

The efficiency of IDLV observed in our and in other models [27], in terms of quantity, persistence, and quality of CD8+ T cell response, could be reasonably considered an excellent beginning for future exploitation of this vector for developing vaccine strategies aimed at inducing CD8+ T cell responses. The possibility to use IDLV in heterologous prime-boost protocols as well as in mucosal vaccine, in order to improve immune response at both systemic and mucosal sites, should be further investigated. Finally, to have the proof of concept that this vector could represent a novel and effective delivery system for vaccine strategies in humans, experiments in the nonhuman primate model of AIDS should be performed by evaluating the strength of the

FIGURE 4: Analysis of cytokine production by intracellular staining (ICS). Results from one representative experiment out of three independent experiments are shown. (a) Splenocytes from mice immunized with IDLV-JRmZ, DNA-JRmZ, IDLV-Empty, and DNA-Empty or from naïve mice were cultured in vitro with Envelope-specific JR-9mer peptide and then stained for IFN γ , TNF α , and IL2. Error bars indicate the standard deviation among four mice of the same group. Data are expressed as percentage of single cytokine-producing T cells by gating the CD8+ T cell population. (b) IDLV-JRmZ vaccination induced high frequency of polyfunctional antigen-specific CD8+ T cells able to simultaneously produce IFN γ , IL2, and TNF α . A representative experiment is shown. The analysis was performed on CD8+ T cells from the mice immunized with IDLV-JRmZ (upper panels) or DNA-JRmZ (lower panels). CD8+/IFN γ -producing cells were gated and analyzed for the production of both TNF α and IL2. Within the dot plots the percentages of single (IFN γ) and double (TNF α and IL2) cytokine-producing CD8+ T cells are indicated. FSC: forward scatter.

immune response induced in terms of both frequency and quality of viral-specific T cells and the ability in controlling the viral challenge.
