Inflammatory bowel disease (IBD) is a group of chronic inflammatory disorders that affect individuals throughout life. Although the etiology and pathogenesis of IBD are largely unknown, studies with animal models of colitis indicate that dysregulation of host/microbial interactions are requisite for the development of IBD. Patients with long-standing IBD have an increased risk for developing colitis-associated cancer (CAC), especially 10 years after the initial diagnosis of colitis, although the absolute number of CAC cases is relatively small. The cancer risk seems to be not directly related to disease activity, but is related to disease duration/extent, complication of primary sclerosing cholangitis, and family history of colon cancer. In particular, high levels and continuous production of inflammatory mediators, including cytokines and chemokines, by colonic epithelial cells (CECs) and immune cells in lamina propria may be strongly associated with the pathogenesis of CAC. In this article, we have summarized animal models of CAC and have reviewed the cellular and molecular mechanisms underlining the development of carcinogenic changes in CECs secondary to the chronic inflammatory conditions in the intestine. It may provide us some clues in developing a new class of therapeutic agents for the treatment of IBD and CAC in the near future.

1. Introduction

Crohn and Rosenberg first reported the UC case associated with colorectal cancer development in 1925 [1], and the association between colitis and colorectal cancer is widely accepted currently. It is assumed that chronic inflammation is a direct cause of CAC; however, it is not until 10 years after disease onset when a risk of colon cancer development in IBD patients becomes significant. The risk is approximately five times higher than in the general population. Eaden et al. reported that the cumulative incidence of colorectal cancer in UC patients was 2% at 10-year, 8% at 20-year, and 18% at 30-year with followup study [2]. The important risk factors include family history of colon cancer, disease duration/extent, and concurrent primary biliary cholangitis [3, 4]. The cancer risk seems to be closely associated with the extent of colonic involvement and length of time since disease onset [5]. To detect microscopic foci of dysplasia or early stage of cancer, IBD patients need to undergo an annual colonoscopy with multiple biopsies. A minimum of 33 samples and a total of 50 or more biopsies will be necessary to achieve a high confidence (90%–95%) of detecting cancerous region(s) [6, 7]. A tremendous amount of effort is currently being directed toward improving colonoscopic technology and developing genetic and serological markers [8]. At this time, however, only a limited amount of data are available for understanding the exact mechanisms of how chronic colitis is connected to the development of colorectal tumors.

The small and large intestines both contain an abundance of luminal antigens, including food products and enteric microorganisms. Intestinal epithelial cells provide an important barrier between the potentially hazardous luminal contents and immune cells in the situated lamina propria [9, 10]. The function of colonic epithelial cells
(CECs) is tightly regulated by many soluble factors derived from enteric bacteria and epithelial cells themselves [11, 12]. CECs actively participate in the detoxification and biotransformation of xenobiotics [13, 14], and the failure of these important functions leads to epithelial cell injury and intestinal inflammation [15]. The development or perpetuation of intestinal inflammation is also closely associated with the induction of several molecules on CECs including Toll-like receptors (TLRs) and tumor necrosis factor receptors (TNFRs) [14, 16, 17]. So far, many animal models of chronic colitis and colitis-associated cancer (CAC) provide evidence that a variety of inflammatory mediators play pivotal and specific roles in the initiation and development of colitis and CAC [18]. In particular, TNF and TNFR ligation activated NF-κB and its downstream cell survival pathways seem to highly contribute to the development of colorectal carcinoma [19]. IL-6 is another important cytokine which controls the transition between innate and acquired immune responses [20], and increased levels of IL-6 have been detected both in human colon cancer patients and murine models of CAC [21]. In addition, mRNA expression of CC-chemokines including CCL-2 (MCP-1) is highly upregulated in the colonic mucosa of IBD patients as well as in the AOM pretreated DSS-colitis model [22–24]. Our group recently identified that one of the mammalian chitinases, chitinase 3-like-1 (CHI3L1/YKL-40), is significantly upregulated in message and protein levels in the colonic mucosa of IBD patients with active inflammation as well as murine models of colitis, [14] and this molecule seems to play an active role in the neoplastic transformation of epithelial cells [25, 26]. Therefore, inflammatory cell infiltration and their secreting soluble mediators are key players in regulating pre-neoplastic growth of CECs in colitis-associated tumorigenesis.

In this paper, we have concisely summarized the previously reported animal models of CAC and will discuss possible roles of inflammatory mediators and their receptors in the chronically inflamed colonic mucosa during the development of chronic inflammation and CAC.

2. Overview: Differences between Sporadic Colon Cancer and CAC

Sporadic colorectal cancer, the major form of colon cancer, occurs in people with little or no family history of the disease. This type of cancer often arises from successive accumulation of mutations in genes controlling epithelial cell growth and differentiation. Genomic instability is important to the development of colon cancer; however, the process that causes this genomic instability is not completely understood. Two major types of genomic instability, chromosomal instability and microsatellite instability (MSI), contribute to colonic carcinogenic processes. MSI-positive colorectal carcinomas can be further divided into those with high (MSI-H) or low (MSH-L) levels of MSI depending on how many markers are unstable on a consensus panel [27]. High-level MSI accounts for approximately 15% of sporadic colorectal cancers, while the remaining 85% are attributed to chromosomal instability [28]. MSI-H colorectal cancers neither exhibit gross cytogenetic abnormalities nor display allelic losses at tumor suppressor loci frequently, and they are not generally aneuploid. Colorectal carcinomas originating by the suppressor and mutator pathways differ in pathological features [29]. These tumors are likely to be present in the proximal colon, demonstrate poor differentiation, have mucinous or medullary features, and display more prominent lymphocytic infiltration compared to microsatellite stable tumors or MSI-L tumors.

As described above, colorectal cancer can be caused by chromosomal instability. This is characterized by widespread imbalances in chromosome number (aneuploidy), caused by defects in chromosomal segregation. Mutations in specific tumor suppressor genes and oncogenes that activate pathways critical for cancer development, which are important for the initiation and progression through the cell cycle, are seen in colorectal cancer [30, 31]. The mitotic checkpoint (the spindle assembly checkpoint) is a major cell-cycle control mechanism that ensures proper chromosome segregation by delaying anaphase progression until all pairs of chromosomes are properly aligned on the metaphase plate. Defects in checkpoint signaling lead to chromosome missegregation and subsequent aneuploidy with abnormal numbers of chromosomes being distributed to daughter cells [32]. The products of two genes, mitotic arrest-deficient (MAD) and budding uninhibited by benzimidazoles (BUB), operate as checkpoint sensors and signal transducers that control sister chromatid separation. The activation of these leads to inhibition of the anaphase-promoting complex (APC/C), a large ubiquitin-protein ligase, and cell-cycle arrest. MAD3/BUBR1, MAD2, and BUB3 associate with APC/C-activating molecule CDC20 to form the mitotic checkpoint complex and induce a conformational change in APC/C, which prevents binding and ubiquitination of its substrates [33]. The APC/C activation leads to degradation of securin (a protein involved in control of the metaphase-anaphase transition and anaphase onset) and activation of separase (a class of caspase-related proteases). Separa regulates a multiprotein complex termed cohesin, which creates physical links between sister chromatids that are maintained until late mitosis. The errors in this system lead to unequal chromatid separation [34]. In colorectal cancer, mutations have been found in hZw10, hZwilch/FLJ10036, and hRod/KNTC, which are kinetochore proteins that function at the spindle checkpoint. Another mutation is observed in Ding gene, which regulates proper chromosome disjunction [35].

Another mechanism leading to chromosome instability is abnormal centromere number and function. Centromeres coordinate mitosis by serving as an anchor for the reorganization of cytoplasmic microtubules into a mitotic spindle apparatus. When extra centromeres are present, they lead to the formation of multiple spindle poles during mitosis, resulting in an unequal distribution of chromosomes. When centromeres cluster, an increased rate of merotelic chromosomal attachment to spindle can cause chromosomal missegregation and ultimately chromosomal instability [36]. A third mechanism is a mutation in Aurora B, a kinase regulating chromosome segregation. An overexpression of Aurora B correlates with advanced stages
of colorectal cancer. This is the catalytic component of the chromosomal passenger complex that regulates accurate segregation of chromatids at mitosis, histone modification, and cytokinesis [37]. Finally, the elevated expression of PIK1 (a serine/threonine kinase which regulates entry into mitosis, centrosome duplication, and transition from metaphase to anaphase, and cytokines) is also observed in colorectal cancer [38, 39]. All of these mutations lead to colorectal cancer through chromosomal instability and aneuploidy.

Chronic inflammatory diseases are associated with an increased risk of cancer, and IBD patients have a higher risk of developing CAC approximately 8–10 years after the initial diagnosis as compared to general population. In addition to genomic instability that underlies the process of tumorigenesis, continuous inflammation in the intestine seems to be a key factor in CAC development since chronic inflammation is associated with elevated levels of proinflammatory cytokines, chemokines, growth factors as well as their receptors, and reactive oxygen species. In particular, oxidative injury, causing widespread DNA damage, leads to the inception of cancer. Crypt fission (duplication of crypts by branching) propagates these heterogeneous DNA changes from one crypt to another. In fact, crypt fission is a natural way to duplicate the heterogeneous changes that are sometimes observed in the crypt units of UC patients. Eventually, some of these changes may induce a growth advantage and clonal expansion of CECs, and some of the mutational changes in one crypt can be found in thousands of adjacent crypts. The final stages of tumorigenesis in the chronic inflammatory setting occur when an accumulation of select mutations allows clonal progression to overtake the balancing forces of cell death and loss [40].

3. Spontaneously Developed Animal Models of CAC

A summary of CAC development in genetically engineered animal models of colitis has been shown in Table 1. We have further discussed some selected models, which are included or not included in Table 1, in this section. Although adenomatous polyposis coli (APC) multiple intestinal neoplasia (min) mice do not develop adenocarcinoma, these mice develop numerous adenomatous polyps throughout the small and large intestine, and therefore, we have included this model in the following section.

3.1. APC-Min Mice Model. APC is a multidomain protein translated from the APC gene and composed of 2843 amino acids, which functions to regulate downstream Wnt signaling by binding to β-catenin and promoting its degradation. APC, along with AXIN, GSK-3β, EBI, and other proteins, forms a complex that binds to β-catenin. This complex formation prevents the nuclear translocation of β-catenin and causes its phosphorylation and, subsequently, its degradation by a proteasome. In this way, APC actually acts as a tumor suppressor gene by preventing the continuous activation of β-catenin. A mutation or loss of APC genes results in the upregulation of transcriptional targets such as c-myc and cyclin D1 [53].

Loss or mutation of APC is an early causative event in familial and sporadic colon cancer pathogenesis. The most common mutations in familial adenomatous polyposis (FAP) are deletions in codons 1309 (10% occurrence) and 1061 (5% occurrence) [54]. The mutations in these same codons account for 30% of germline mutations. The majority of germline mutations found in FAP patients are nonsense mutations, which cause the formation of a truncated protein because of the insertion of an early stop codon. Most of the mutations to APC represent truncating mutations, of which, 46% are small deletions, 10% are small insertions, 28% are nonsense mutations, and 13% are gross alterations. More than 60% of APC mutations are found in the mutation cluster region (MCR, amino acids 1284–1580), the region that is most important for the downregulation of β-catenin and for the pathogenesis of colorectal cancer. Many of these mutations lead to the generation of a truncated protein, which causes the loss of APC protein function [54, 55].

APC<sup>min</sup> mice, homozygous for the mutation, experience embryonic lethality. However, those that are heterozygous for the mutation are viable and develop more than fifty adenomas in the intestinal tract. The small intestine is most commonly the site of these tumors. These mice can also develop a variety of lesions in other organs such as desmoids tumors, epidermoid cysts, and mammary tumors [56]. Most APC<sup>min</sup> mice only survive to 120 days, at which point they die of the excess tumor formations in their small intestines [57]. In APC<sup>min/+</sup> mice, different areas of the gene, such as the EB1/RP1 binding area, DLG/PTP-BL binding area, nuclear export/import signals, the CDK consensus phosphorylation site p34-cdc2 binding, the β-catenin binding site, β-catenin downregulation site, and Axin/conductin binding site, are missing by truncational mutations [55]. Because APC is an important molecule in the formation of colorectal cancer, mouse models have been developed to study the physiological and biological function of this protein in polyp formation. APC<sup>min/+</sup> mice have been widely utilized for studying the effects of this protein under controlled experimental conditions. APC<sup>min/+</sup> mice were treated with ethynitrosourea (ENU) to induce colitis, and multiple intestinal neoplasia was observed carrying a nonsense mutation [56, 58].

The APC<sup>min</sup> mutation initiates mitotic defects in histologically normal crypt cells of the murine small intestine, in which misoriented spindles, misaligned chromosomes, and tetraploid cells are frequently observed. In addition, changes in crypt size, cell proliferation, and apoptosis have been observed [55]. The cells in these APC deficient crypts show reduced crypt to villus migration and differentiation. Chromosomal instability resulting in losses and/or gains of chromosomal regions and microsatellite instability, which results from mismatch repair deficiency, is another change observed in APC deficient mice. Microadenoma formation, visible in these mice, could result from DNA hypomethylation.

Secretory Phospholipase 2 (sPLA2) is a key enzyme involved in the release of arachidonic acid from membrane lipids in the synthesis of prostaglandins. The loss of sPLA2 increases APC driven tumorigenesis. In addition, PLA2g4 (group 4 cytosolic phospholipase A2 catalyzes the hydrolysis
of membrane phospholipids to release arachidonic acid) suppresses tumor multiplicity in APC<sup>min/+</sup> [57]. Although APC<sup>min/+</sup> mouse is a good model of colitis, there are differences between the progression of disease in mice and humans. In APC<sup>min/+</sup> mouse model, the polyp formation occurs mainly in the small intestine, while this formation occurs mainly in the colon in humans. In addition, there is very little or no invasion of the submucosa by tumors in APC<sup>min/+</sup> mice, and the tumors do not develop into adenocarcinomas [59].

APC<sup>min</sup> has interactions with other genes as well. Previous studies have shown that one of the downstream targets of Wnt signaling, cyclin D1, was not upregulated immediately after APC loss and did not contribute to the early phenotype in colon cancer. In contrast, the loss of both proto oncogene c-myc and APC has a crucial role in early stages of sporadic colorectal carcinoma development. As argued by some investigators, loss of APC function is typically an early stage event in the pathogenesis of sporadic colorectal carcinoma, but APC mutation itself seems to be a later stage (from high-grade dysplasia to adenocarcinoma) of tumor progression in CAC, suggesting APC mutation may not be the universal initiating event in colon cancer [27]. However, loss and/or truncation of APC still highly contributes to the cause of mitotic spindle defects that, upon somatic inactivation of other chromosomal instability

genes (e.g., spindle and cell-cycle checkpoint genes, DNA repair, and telomerase maintenance), underlie aneuploidy as observed in the majority of colorectal cancer [60].

3.2. IL-10 Knockout (KO) Mice Model. IL-10 is a key regulator of the pathogenesis of IBD. Patients with mutated IL-10 signaling systems show early and aggressive development of systemic inflammation including IBD. IL-10 KO mice also develop spontaneous colitis and CAC with aberrant Th1 cytokine production. The histopathology of chronic colitis in IL-10 KO mice is characterized by epithelial hyperplasia, inflammatory infiltrates in the mucosa and submucosa, and crypt abscesses [61]. The inflammatory infiltrates consist of small to moderate numbers of neutrophils and eosinophils and crypt abscesses [61]. The inflammatory infiltrates in the mucosa and submucosa, and slight loss of nuclear polarity consistent with adenocarcinoma [61]. No cells in the intestinal walls, fibrosis, and slight loss of back-to-back growth of glands, small lesions so epithelial and may involve the intestine transmurally. Six-month-old IL-10 KO mice crossed to human MUC1-transgenic mice developed much more severe colitis with a significantly higher incidence of colon cancer as compared to IL-10 KO mice [64]. MUC-1 has been reported to be overexpressed in IBD and adenocarcinoma, while its expression levels in normal and healthy CECs are low. Interestingly, vaccination against MUC1 delays IBD onset and also prevents CAC development in these mice, suggesting that the induction of MUC1-specific adaptive immune responses, such as anti-MUC1 IgG and anti-MUC1 CTL, regulate local and systemic immunity by eliminating abnormal MUC1-positive cells in the IBD colon [64].

The development of CAC in IL-10 KO mice has been demonstrated in C57BL/6/129-Ola mixed background mice. These IL-10 KO mice have a 25% incidence of developing adenocarcinoma after 3 months of age. After 6 months of age, they have a 60% incidence of adenocarcinoma [61]. Similarly, it was found in another study that IL-10 KO mice develop tumors, the majority of which are invasive adenocarcinomas, between 25 and 35 weeks of age [64]. Finally, a third study showed the incidence of adenocarcinomas was 14% at 9 weeks of age and 65% at 10–31 weeks of age [62]. When recombinant IL-10 was administered to these mice, the incidence of adenocarcinoma decreased from 67% to 28%. In addition, the background of the mice influences the incidence of adenocarcinoma; IL-10 KO Balb/c, IL-10 KO 129 SvEv, and IL-10 KO C57BL/6 have incidences of 29%, 67%, and 0%, respectively, at 3 months of age [39]. IL-10 KO mice in 129SvEv background showed epithelial extension/invasion mainly in the ascending colon and subsequently developed adenocarcinomas at 6 months of age without showing any signs of metastatic disease [65].

The development of adenocarcinoma in IL-10 KO mice seems to be associated with colonic bacterial infection [66]. IL-10 KO mice infected with Helicobacter typhlonius had a 40% incidence of invasive adenocarcinoma, and the pups born to these mothers, as well as mice infected as pups, had an 18% incidence of colon cancer. In contrast, mice infected with Helicobacter rodentium had a 0% incidence of invasive adenocarcinoma. Interestingly, however, pups born to these mothers and mice infected as pups had an incidence of 12%. Finally, mice infected with both types of bacteria had a 57% incidence of invasive adenocarcinoma. It is hypothesized that the bacteria infect the mice by burrowing through the mucus to grow adjacent to the intestinal epithelial surface, where they degrade the barrier properties. This causes injuries of bacterial antigens into the mucosa, which causes an immune response that in turn leads to the development of IBD and subsequently adenocarcinoma in the host [66].

AOM and DSS treatment promotes inflammation-mediated colonic tumor growth in IL-10 KO mice [67]. Furthermore, Helicobacter hepaticus infection accelerates AOM-induced tumorigenesis compared to AOM treatment alone in IL-10 KO mice [68].

3.3. Gα12 KO Mice Model. G proteins (guanine nucleotide-binding proteins) are signal transducing proteins that couple a large family of receptors to effectors such as adenyl cyclase, phospholipase C, and ion channels [69]. Receptor-activated G proteins are subsequently bound to the inner surface of the cell plasma membrane, which consists of the Gα and Gβγ subunits. There are four classes of Gα subunit, namely, GαS, Gαi3, Gαq/11, and Gα12/13. Gαi inhibits the production of cAMP from ATP. Activation of the Gαi protein mediates colonic tumor growth in IL-10 KO mice [67]. Further, IL-10 KO mice in 129SvEv background showed epithelial extension/invasion mainly in the ascending colon and subsequently developed adenocarcinomas at 6 months of age without showing any signs of metastatic disease [65].
However, Hornquist’s group showed that long-term (three times/week for 9 weeks) blockade of α4 integrin significantly increased the severity of colitis as well as cancer incidence and also showed decreased levels of total IgA and IgG level in the sera of Gai2 KO mice [75]. Therefore, caution needs to be made upon applying a long-term treatment with anti-α4 integrin antibody in clinical trials.

3.4. Chronic Colitis and CAC in Cotton Top-Tamarin (CTT). CTT is one of the best primate models for studying colitis and CAC although it is not currently used because of the risk of extinction.

CTT was previously an important primate model for the study of colitis and CAC because, like humans, it spontaneously develops colitis which often leads to colorectal cancer. The CTT’s natural habitat is a rain forest located in northwestern Colombia, South America [76]. CTT were initially imported to the United States in the 1960s and were used for infectious studies with Herpes simianus, Herpes atelis, and the Epstein-Barr virus. However, all research studies were withdrawn when the CTT were placed on the endangered species list in 1977. During the reconstruction effort of the CTT breeding colonies, it was found that chronic ulcerative colitis and colonic adenocarcinoma were to be major health problems for this species [77, 78]. Approximately 80% of the captive CTT developed active colitis that would eventually lead to low-to-high grade dysplasia and colonic adenocarcinoma [76]. Another group also identified that 65.4% of captive CTT showed severe colitis but none in wild CTT; and 19.5% of captive CTT showed moderate colitis but only 13% in wild CTT [79]. In CTT, species-related susceptibility and infection (e.g., corona viruses, Campylobacter, Helicobacter, and enteropathogenic Escherichia coli) seem to be one of the causes of chronic colitis [77, 80]. Other extrinsic/intrinsic factors include disruption of the immune system, family history of CTT, short-chain fatty acids (SCFAs), carcinoembryonic antigens (CEAs), and environmental stress. A unique member of Helicobacter is found in the intestines and feces of CTT with chronic colitis. This particular strain lacks urease activity and fails to hydrolyze alkaline phosphatase. The pathogenicity remains unknown, but since the Helicobacter family is considered to be responsible for inflammation and hyperplasia of epithelial cells and predisposes an individual to neoplasia, it is conceivable that this novel Helicobacter may play a role in contributing to UC and CAC of CTT [79].

Watkins et al. utilized a humanized anti-TNFα monoclonal antibody (CDP571) in treatment for the spontaneously developed colitis in CTT, and showed rapid improvement in clinical parameters [81]. This result strongly suggests that TNFα overproduction is likely a critical pathogenic factor in spontaneously developed chronic colitis in CTT. Several clinical studies have established that a chimeric (75% mouse/25% human) anti-monoclonal antibody (Infliximab) is beneficial in the treatment for IBD [82, 83]. In particular, Infliximab is an effective maintenance therapy for fistulizing CD [84] and is useful for the treatment of mucosal ulceration associated with CD [83].

It is also noted that disrupting inflammatory mediators (neutrophils, lymphocytes, monocytes, eosinophils, and mast cells) are involved in the development of chronic colitis. Two research groups elegantly demonstrated that administration of monoclonal antibodies directed against either E-selectin or integrin α4 (one of the subunits of VLA4) attenuated colitis in CTT [73, 74]. Since the followup animal studies by other groups also confirmed an important role of α4 integrins in the migration of circulating leukocytes into the intestinal mucosa, a clinical trial using Natalizumab (a humanized anti-α4 monoclonal antibody) for CD was initiated, and showed a statistically significant effect in the initial trial [71, 85]. However, the following clinical trial could not confirm the benefit [86]. In addition, during the treatment with Natalizumab, some patients developed progressive multifocal leukoencephalopathy secondary to reactivation of the JC virus, a human polyomavirus that is typically acquired during childhood and remains latent in the kidneys and possibly other sites in up to 80% of the adult population [87]. Furthermore, blockade of α4 integrin exacerbated the chronic colitis and increased cancer incidence in a Gaα5 KO mice model [75]. Based on these results, efficacy of Natalizumab for CD is highly questionable, and it carries a potential risk of severe complications [88].

4. Chemically Induced Colitis-Associated Cancer Model

4.1. Chronic DSS-Induced CAC Model. To reproduce the clinical course of UC experienced in humans, which is characterized by the spontaneous onset of active inflammation with separated periods of disease inactivity, DSS is administered for 3–7 days in mice to induce inflammation of the colon, followed by regular water administration for 1–2 weeks to permit healing of the colonic mucosa. Several “cycles” of DSS administration have also been used in order to augment carcinogenesis as observed in chronic ulcerative colitis patients. Squamous metaplasias of the rectal mucosa, squamous papilloma, adenoma, and adenocarcinoma have been observed in the treated mice. During the development of DSS-induced colorectal tumor, several genes, and molecules play pivotal roles in the pathogenesis. We have summarized some of the important factors in the following section as well as in Tables 2 and 3.

4.1.1. APC. The APCmin/+ mutation is found in 80% of sporadic colorectal cancers and is found in 4%–27% of CAC [109]. To test the effects of this gene on CAC development, colitis was induced in APCmin/+ mice. These APC+/min mice (C57BL/6) strain were treated with 2 cycles of DSS. The first cycle of DSS administration consisted of 4 days of 4% DSS followed by 17 days of regular water. The second cycle consisted of 3 days of 4% DSS followed by 18 days of regular water. In another experiment, the mice (female, B6 background) were treated with 4 cycles of DSS with each cycle consisting of 4 days of 4% DSS and 17 days of regular water. Through these treatments, a two-fold (50% to 100%) increase in tumor incidence was found [100].

The untreated control APC^{min/+} mice had no evidence of invasive colorectal cancer while 40% of the DSS-treated APC^{min/+} mice developed colorectal cancer. The incidence of adenocarcinoma in WT mice exposed to DSS was 12.5% and the mean number of tumors per tumor-bearing mouse was 1.0. All the DSS-treated WT mice had polyoid tumors with no evidence of flat lesions. These findings indicate that both the mutation of APC and inflammation accelerate the formation of colitis-associated dysplasia and their progression into invasive carcinoma. While inflammation is an augmenting factor for colorectal cancer development, loss of heterozygosity of the APC gene is also important in the formation of colorectal neoplasia [100].

4.1.2. p53. The loss of p53 is one of the early mediators in CAC [112, 113]. In the studies, DSS-colitis was induced in p53+/+, p53+/-, and p53 KO mice in C57Bl/6 background. The mice were treated with 3 to 4 cycles of DSS followed by 120 days of regular water treatment after the final cycle of DSS administration. Each cycle consisted of 4 days of 4% DSS followed by 17 days of regular water. There were no colorectal lesions in untreated p53+/+, p53+/- or p53 KO mice, while colorectal cancers developed in 57% of the DSS-treated p53 KO mice, 20% of p53+/−, and 20% of p53+/+. The DSS-treated p53 KO mice had a larger number of lesions including cancers and dysplasias per mouse as compared to p53+/- or p53+/+ mice. In the p53 KO group, 38.5% of the mice exhibited flat cancers, 46.1% flat dysplasias, 15.4% polyoid cancer, and 0% polyoid dysplasias. In contrast, the DSS-treated p53+/- mice showed more polyoid neoplasms: flat cancers were seen in only 16.7% of the mice, flat dysplasias in 0%, polyoid cancers in 5.6%, and polyoid dysplasias in 77.8%. Interestingly, all the DSS-treated p53+/+ mice showed polyoid dysplasias. Therefore, flat cancers...
are highly associated with p53-deficient genotype while polypoid dysplasias are associated with p53+/− and p53+/+ genotypes. In addition, nuclear translocation and mutation of β-catenin were observed only in polypoid lesions (91% and 43.7%, resp.). This result strongly suggests that the loss of p53 enhanced induction of CAC, and particular flat cancer-lesions, and dysregulation of β-catenin signaling plays an important role in the formation of polypoid-dysplastic lesions in the p53 model of colitis-associated neoplasia. Chang et al. used C57BL/6 x CBA mice and showed the similar results. After treatment with 2 cycles of 4% DSS (7 days DSS treatment with 14 days interval), neoplastic lesions developed in 100% of p53 KO, 46.2% of p53+/−, and 43.7%, resp.). This result strongly suggests that the protein 39.

4.1.4. Msh2. Msh2 is one of the mismatch repair genes that is frequently mutated in hereditary nonpolyposis colon cancer (HNPCC). It is unclear whether loss of mismatch repair contributes to development of colitis associated neoplasia in humans [119, 120]. In a study, colitis was induced in Msh2 KO, Msh2+/−, and Msh2+/+ mice on a 12910LA x C57BL/6 background using DSS treatment. There was no difference in severity of chronic colitis as well as incidence of colonic neoplasms among the different genotypes. After 5 cycles of DSS treatment, 12.5% of Msh2 KO, 8.0% of Msh2+/−, and 46.7% of Msh2+/+ mice developed high-grade dysplasia. Similarly, colonic adenocarcinoma of the mucinous type were seen in 13.3% of Msh2 KO, 8.0% of Msh2+/−, and 16.7% of Msh2+/+ mice although the majority (77.8%) of the Msh2 KO mice tumors were microsatellite instability high opposed to none of the Msh2+/− and Msh2+/+ mice. However, future studies using these mice may elucidate the role of the DNA mismatch repair in colitis-associated neoplasia in humans [121].

4.1.5. Brp39. Brp39 is a mouse homologue of Chitinase 3-like-1 (CHI3L1, YKL-40, HC-gp39). CHI3L1 is induced on CECs and macrophages under inflammatory conditions and plays a key role in host-microbial interactions by enhancing the adhesion and invasion of bacteria into the CECs [122]. To examine the biological function of this molecule in the development of CAC, our lab has developed an AOM-pretreated chronic DSS-induced CAC model using Brp39 KO and Brp39+/+ mice. Brp39 KO mice were more susceptible to the chronic DSS colitis with increased proinflammatory cytokine production and inflammatory cell infiltration in the colonic mucosa as compared to Brp39+/+ mice. Subsequently, the Brp39+/+ mice had a higher incidence of CAC (87.5%) than Brp39 KO mice (37.5%), suggesting that Brp39 plays a key role in the development of CAC.

4.2. Iron Supplemented DSS Model. Iron-deficiency anemia is a frequent complication in UC patients due to colorectal bleeding, and these patients are clinically treated with iron

supplements [123]. However, Seril et al. reported that dietary iron supplementation enhanced the development of CAC in a 1% DSS-induced colitis model, and the histology of the tumors was fairly similar to that of human CAC [96]. In the chronic DSS-treated mice, 88% of iron-enriched diet fed mice developed colorectal tumors while only 19% of the control developed the tumors, suggesting that dietary iron may enhance the development of CAC in IBD patients presumably by augmenting oxidative and nitrosative stress [96, 108].

4.3. Carcinogen-Induced CAC Model. There are effective chemical agents, which directly or indirectly, induce colorectal tumors in laboratory animals. Many researchers use azoxymethane (AOM, methyl-1-(3-methyl-2-butenyl)-1H-imidazo[4,5-f]quinoxalin-1-ium), 1,2-dimethylhydrazine (DMH), and/or methyl azoxy methan (MAM) acetate in the animal models of CAC. AOM is the most widely used carcinogen in the colon. AOM- or DMH-induced colorectal cancer in rats shows many similarities to human colorectal cancer; however, there are some differences between the two. Although many human colorectal cancers arise from adenomatous polyps, AOM- or DMH-induced rat adenocarcinoma in the colon develop in the background of flat mucosa without polyp formation [124]. In addition, it has been reported that the incidence of metastasis is relatively low in AOM- or DMH-induced adenocarcinoma, while colorectal cancer patients have an approximate 50% metastatic rate in regional lymph nodes at the time of diagnosis [102]. Despite these differences, the chemical-induced CAC models are widely used, and have provided valuable information regarding the pathogenesis of CAC.

AOM is the oxide of azomethane and is used in cancer research to enhance the formation of colorectal tumors in rodents. AOM augments the expression of cyclooxygenase (COX)-2 (but not COX-1) in colonic tumors [125], which, in turn, suppresses transforming growth factor-β receptor 2 (TGFBR2) expression in CECs [126] and activates intrinsic tyrosine kinase of epidermal growth factor receptor (EGFR) [127] in laboratory rodents. After treatment with subcutaneous or intraperitoneal injection of AOM (10 mg/kg body weight, in general) followed by multiple cycles of DSS, the treated mice developed colonic tumors within a relatively short time period [101, 102]. AOM/DSS-induced colonic dysplasia and adenocarcinoma showed nucleic translocation of β-catenin and positive staining for COX-2 and inducible nitric oxide synthesis, but no immunoreactivity to p53 [128]. AOM-treated APC<sup>min+</sup> mice have also shown an enhanced expression of COX-2 in the early phase of colitis-associated tumors [42]. Interestingly, molecular analysis clearly demonstrated that AOM exposure induces the mutations in codons 33 and 34, while DSS exposure induces mutation in codon 32 of the mouse β-catenin gene [105]. A single dose of various colon carcinogens including AOM and DMH, followed by exposure to 2% DSS just for one week is effective enough to induce colonic tumors [104, 105], suggesting that there is no correlation between the severity of colitis and development of colonic tumors. Exposure to bacteria (by transferring from germfree to a specific pathogen free condition) followed by repeated AOM treatment for six times induces CAC in IL-10 KO mice, but not in WT mice. The results support the notion that inflammation itself plays an important role in the initiation and progression of CAC [129].

4.4. Carrageenan-Induced CAC. Carrageenan (CGN) are high molecular weight (>200 kDa) gelatinous polysaccharides, which are extracted from red seaweeds, and are widely used as thickening and stabilizing agents in the food or other industry products. Although the native form of OGN is thought to be harmless, a degraded form of CGN (so called Poligeenan or dCGN) with acid treatment at high temperature, around 80°C, reduces the molecular weight (<50 kDa) and may have toxic effects in animal models including rats, guinea pigs and monkeys by causing colonic ulceration and neoplasia in the gastrointestinal tract [92]. CGN-induced squamous metaplasia persisted in almost all experimental rats and progressed irreversibly, and the tumors included adenoma, adenocarcinoma, squamous cell papilloma, and squamous cell carcinoma [91]. However, the role of both CGN and dCGN as carcinogens still remains controversial. Tobacman’s group demonstrated through in vitro studies that the native form of CGN induces IL-8 production in NCM460 human CEC line by enhancing the activation of NF-κB pathway [130, 131]. Furthermore, dCGN induces cellular aggregation and enhances ICAM expression and TNFa production in monocytes through NF-κB activation both in vivo and in vitro [93]. These studies suggest that both native and degraded CGN may have a pronounced effect on the exertion of an inflammatory pressure on colonic mucosal cells including CECs and monocytes/macrophages.

5. Involvement of Soluble Mediators in CAC

A complicated immune network is involved in CAC development. To understand this mechanism in CAC, we have summarized the main interacting cells and soluble factors in Figure 1, and major signaling pathways involved in CAC development in Figures 2 and 3. We have also summarized each major factor in CAC development in this section.

5.1. Proinflammatory Cytokines/Factors

5.1.1. TNFa. TNF produces multiple effects including altered cell proliferation and cell death through distinct signaling cascades resulting from binding to TNFR type-I (TNFR1) and type-II (TNFR2) [132]. In general, cell death, altered target gene transcription, and cytokine production are mediated by TNFR1, while engagement of TNFR2 has an antiapoptotic effect, acting through an NF-κB pathway [133]. These receptor-mediated signalings regulate inflammatory cell infiltration in the lamina propria, epithelial/mucosal damage, and cytokine expression in colonic mucosa in many animal models of colitis and CAC [18]. In fact, TNFR1 knockout (KO) mice showed a much milder form of colitis with a reduced incidence of CAC in response to the AOM pretreated DSS-induced colitis as compared to WT mice [134].
TNF initiates and perpetuates many inflammatory reactions and efficiently recruits activated inflammatory cells to the site of injury or inflammation [135]. TNF also efficiently activates NF-κB, MAPK and cell-death signaling pathways. Dysregulated TNF production has been identified in various inflammatory disorders including rheumatoid arthritis, IBD, psoriasis, ankylosing spondylitis, and refractory asthma. TNF-blocking agents have been widely utilized for treatment of said disorders. In particular, these agents show a significant efficacy in refractory IBD compared to other anti-inflammatory and/or immunosuppressive medications [136]. Etanercept, a recombinant fusion protein consisting of the extracellular ligand-binding region of recombinant human TNFR attached to the constant (Fc) region of human IgG1, binds to circulating TNF, inhibits its attachment to TNFRs, and efficiently blocks the TNF-mediated inflammatory pathway in rheumatoid arthritis [137]. However, while it efficiently blocks the tumor formation in AOM-induced CAC model, the efficacy of Etanercept in IBD is quite limited as compared to monoclonal antibodies directed against TNFα (e.g., Infliximab) [138]. In contrast, anti-TNF antibodies show unclear efficacy (anti- or procarcinogenic effects) in colorectal cancer development [139, 140].

5.1.2. IL-6. IL-6 (also known as IFN-β or B-cell stimulator factor-2) plays an important role in the transition from acute inflammation to chronic colitis, as well as innate immunity to acquired immunity [141]. IL-6 is mainly produced by macrophages after being exposed to specific microbial molecules, so called pathogen associated molecular pattern (PAMPs). IL-6 binds to a cell-surface receptor complex, which consists of an IL-6Rα chain (CD126) and the signal-transducing component gp130 (CD130). The ligand-receptor interactions initiate signal transduction cascades through transcription factors, Janus kinases (JAKs) and Signal Transducers and Activators of Transcription (STATs) [142]. In addition, IL-6 enhances the differentiation of...
Figure 2: The JAK/STAT3 signaling pathway transmits information from cytokine/chemical signals outside the cell, through the cell membrane, and into the gene promoters on the DNA in the cell nucleus, which causes DNA transcription and activity in the cell. After JAK is activated by autophosphorylation, STAT3 protein then binds to the phosphorylated receptor. STAT3 is phosphorylated and translocated into the cell nucleus, where it binds to DNA and promotes transcription of genes responsive to STAT. TGF-β controls proliferation, cellular differentiation, and it acts as an antiproliferative factor in normal epithelial cells, and at early stages of oncogenesis. In the SMAD pathway, the TGF-β dimers bind to a type-2 receptor which recruits and phosphorylates a type-1 receptor. The type-1 receptor then recruits and phosphorylates a SMAD. This SMAD then binds to the common SMAD and forms a heterodimeric complex. This complex then enters the cell nucleus where it acts as a transcription factor for the various genes, including those to activate the MAP Kinase pathway, which triggers apoptosis. The TAK1-NLK-STAT3 pathway cascade participates in TGF-β-mediated mesoderm induction. Finally, MyD88 is a universal adaptor protein that is used by most of TLRs to activate the transcription factor NF-κB. These signals are closely associated with colitis-associated cancer formation. The abbreviations used in this figure are: Erk, extracellular signal-regulated kinases (ERK); HAD, histone deacetylase; IKK, IκB inhibitor; IRAK, IL-1 receptor associated kinase; JAK, Janus kinase; NLK, nemo-like kinase; MAPK, microtubule-associated protein kinase; MEK, mitogen activated protein kinase; mTOR, mammalian target of rapamycin; MyD88, myeloid differentiation primary response gene 88; PI3K, phosphoinositide 3-kinase; STAT, signal transducer and activator of transcription; TAK, TGF-β activated kinase; TBR, TGF-β receptor; TCF, T cell factor; TGF, transforming growth factor; TLR, Toll-like receptor.

Th17 cells under a combination with immunosuppressive cytokines (e.g., TGFβ) [143, 144]. IL-6 expression is significantly increased in IBD and in murine models of colitis, and the blocking of IL-6 signaling significantly inhibits the severity of colitis in murine models [145–150]. A randomized pilot study of humanized anti-IL6R in active CD patients showed no beneficial effect in improvement with endoscopic and histologic examination, although an 80% improvement of clinical symptoms in patients who were treated with the Ab as compared to 31% improvement in placebo patients was noted [151].

IL-6 production is highly upregulated in colorectal-tumor developing APCmin mice and animal models of CAC [152, 153]. In human, increased serum levels of IL-6 production have been identified in colorectal cancer patients [154]. IL-6 expression is mainly regulated by NF-κB activation, and IL-6 acts on both CECs and immune cells [155, 156]. Effects of IL-6 are mediated mainly by transcription factor STAT3 activation in cancer cells, and STAT3-mediated cell activation further promotes cell-survival and cell-cycle progression of premalignant as well as cancer cells by inducing expression of antiapoptotic genes (e.g., Bcl2, Bcl-xL) and proliferation-associated genes (e.g., c-Myc, Cyclin D1) [157, 158]. Interestingly, inhibition of IL-6 signaling significantly reduced tumor development in AOM-induced CAC model, suggesting IL-6 trans-signaling plays a pivotal role in the development of colon cancer [159]. Li et al. recently demonstrated that expression of suppressor cytokine signaling 3 (SOCS3), which is the major negative regulator of STAT3, was significantly reduced in patients with UC-accompanied with colon cancer as compared to inactive UC or active UC, who had no colon cancer progression [160]. Therefore, IL-6 trans-signaling and STAT3 activation must be a potential and attractive therapeutic target for CAC progression.

5.1.3. IL-23/IL-12/IL-17. IL-23 is a heterodimeric cytokine consisting of two subunits, p40 (which is shared with IL-12) and p19 (also called as IL-23α subunit). IL-23 binds to a specific receptor, which is formed by IL-12Rβ1 and IL-23R. Both IL23 (p19/p40) and IL-12 (p35/p40) can activate the STAT4 transcription factor, and subsequently stimulate the production of IFNγ. In addition, IL-23, TGFβ and IL-6 con jugationally stimulate naïve CD4+ T cells to differentiate into Th17 cells, which produce the proinflammatory cytokine IL-17 [161]. IL-23 plays an important role in the inflammatory response against infection, and the expression is increased in IBD [162, 163] and in colon cancer [164]. Shan et al. showed antitumor activity of IL-23 in a murine model of cancer, in which murine colon carcinoma cells retrovirally
Figure 3: Wnt signaling plays central role in embryogenesis and human diseases including cancers. Wnt ligands to 7-transmembrane domain receptor Frizzled, which transactivates EGFR signaling by MMP-mediated release of soluble EGFR ligands. Activated EGFR transactivates β-catenin via receptor tyrosine kinase-PI3K/Akt pathway, and β-catenin also forms heterodimer with EGFR and further activate EGF pathway. Direct activation of EGFR utilizing EGF-family ligands induces CHI3L1 expression, which binds to a putative receptor on cell membrane and leads to PI3K-mediated phosphorylation of Akt followed by β-catenin transactivation. As shown in this figure, Wnt and EGFR pathways have been reported to closely interact in tumorigenesis by crosstalking and coactivating tumor progression. The activation of ASK1, following of TNF/TNFR1 and/or IL-1/IL-1R ligation, activates SAPK/JNK and MAPKp38 followed by increased production of MMPs and cytokines. NF-κB signal is also activated by TNF and IL-1, which is highly involved in the development of chronic colitis as well as colitis-associated cancer formation. The abbreviations used in this figure are: ASK-1, apoptosis signal-regulating kinase 1; ATF-2, activating transcription factor 2; BAD, Bcl2-antagonist of cell death; Bcl2, B-cell lymphoma 2; CHI3L1, chitinase 3-like-1; EGF, epidermal growth factor; Elk-1, Ets like gene 1; GSK3β, glycogen synthesis kinase 3 beta, Lef-1/TCF, lymphoid enhancer-binding factor-1/Tcell factor; IKK, IκB kinase; IRAK, IL-1 receptor associated factor; LPR5/6, lipoprotein-related receptor 5 and 6; PI3K, phosphoinositide 3-kinase; SAPK/JNK, stress-activated protein kinase/c-Jun NH2-terminal kinase; TBP, TATA-binding protein; TNFR1; Tumor necrosis factor receptor 1; TRADD, TNF receptor 1-associated death domain; TRAF, TNF receptor associated factor.

transduced with mouse IL-23 gene were subcutaneously injected [165]. Interestingly, IL-23 secreted by tumor cells efficiently suppressed the growth of tumor and the survival of mice by enhancing the production of IFNγ, IL-12, and TNFα [165]. IL-23 and Th17 cytokines act coordinately to maintain the balance between tolerance and immunity in the gastrointestinal tract [166].

5.1.4. Cyclooxygenase (COX). COX is an important enzyme, which is responsible for forming prostanoids including prostaglandins. COX can convert arachidonic acid to prostaglandin H₂, the precursor for prostaglandins, which act on a variety of cells and cause multiple actions including, but not limited to, muscular constriction and mediation of inflammation. So far, there are three COX isozymes: COX-1, COX-2, and COX-3 (a splice variant of COX-1). COX-1 is found in most mammalian cells constitutively, while COX-2 is undetectable in most normal cells but becomes abundant in macrophages and other cells under inflammatory conditions.

It has been reported that COX-2 is upregulated in various malignant cells and has a key role in inflammation-associated carcinogenesis. Oshima et al. first demonstrated the role of COX-2 in colorectal tumorigenesis in mice carrying a mutant Apc gene encoding a product truncated at 716 (ApcΔ716), a mouse model of human familial adenomatous polyposis [167]. Another report also has suggested that intestinal epithelial cells upregulated Cox-2 expression in a TLR-4 and MyD88-dependent fashion. This signaling is required for optimal proliferation and protection against apoptosis in the injured intestine, while TLR4 may lower the threshold for carcinogenesis in an AOM/DSS-induced cancer model [168]. In the same model, endogenous administration of PGE2 treatment increased mucosal expression of COX-2, thus PGE2 involves in the TLR-4-mediated intestinal tumorigenesis [169].

COX inhibitors are compounds that can efficiently block the action of COX enzymes. Nonsteroidal anti-inflammatory drugs (NSAIDs) are widely utilized inhibitors for both of COX-1 and COX-2 enzymes. NSAIDs that selectively block the COX-2 enzyme but not COX-1 are called COX-2 inhibitors that have less adverse effects. Selective COX-2 inhibitors significantly reduced the number and size of intestinal polyps in ApcΔ716 mice [167, 170] and the
occurrence of neoplasia in p53-deficient mice treated with DSS [171]. Celecoxib, another COX-2 inhibitor, prevents a wide variety of cancers including animal models of urinary bladder cancers [172], human breast cancer cells [173], human colon cancer cells [174], and human lung cancer [175], while clinical trials participants taking celecoxib had a significant increase in their blood pressure, which may have affected their heart disease risk [176, 177].

Besides the NSAIDs, salicylates, such as aspirin (acetylsalicylic acid), methyl salicylate and sodium salicylate, are widely used as drugs for their analgesic, anti-inflammatory, and antipyretic effects. Salicylates, including aspirin, inhibit prostaglandin synthesis, and aspirin is able to irreversibly inactivate both COX-1 and COX-2. More recently, it has been reported that regular intake of aspirin has been associated with a decreased incidence of colon cancer [178]. Some double-blind randomized placebo-controlled clinical trials indicate that daily consumption of aspirin (75–80 mg) can lead to a 40%–50% decrease in the risk of developing colon cancer [179, 180]. The aspirin-mediated antitumor effect is also supported by animal models, including 1,2-dimethylhydrazine-induced colon cancer model in Sprague-Dawley rats [181], AOM-induced colon carcinogenesis in F344 rats [182], and intestinal adenomas model in APC<sup>min/+</sup> mice [183]. In addition, antineoplastic effect can be achieved by eating salicylic acid-rich foods (e.g., a wide range of fruit, vegetables, herbs, and spices) at concentrations as low as 100 nM/mL [184].

5.2. Regulatory Factors

5.2.1. IL-10. IL-10 (also known as human cytokine synthesis inhibitory factor; CSIF) is a key anti-inflammatory cytokine produced primarily by monocytes, T cells and B cells. IL-10 can block NF-kB activity, and also regulates the JAK-Stat signaling pathway [185]. IL-10 interacts with IL-10 receptor a subunit (IL-10RA) and inhibits the synthesis of proinflammatory cytokines such as IL-6 [18, 186]. IL-10 KO mice develop spontaneous colitis, which is similar to human IBD, in particular CD [187]. These mice also develop colitis-associated cancer, which is associated with the overproduction of Th1 cytokine [61]. AOM and DSS treatment promotes inflammation-mediated colonic tumor growth in IL-10 KO mice [67]. Furthermore, Helicobacter hepaticus infection promotes AOM-induced tumorigenesis as compared to AOM treatment alone in IL-10 KO mice [68]. We have summarized chronic colitis and CAC development in IL-10 KO in Sections 2 and 3 in this review.

5.2.2. Transforming Growth Factor (TGF)-β. TGF-β has an antiproliferative effect in normal epithelial cells as well as early stage of oncogenesis [188]. TGFβ has three protein precursors, the so-called TGF-β1, -β2, and -β3, and each have an N-terminal short (20–30 amino acids) signal peptide. The C-terminal region becomes the mature TGF-β protein, which makes a homodimer to produce an active molecule [189]. There are three TGF-β receptors: types I and II have a high affinity for TGF-β1, and type III has a high affinity for both TGF-β1, and -β2. In most of cases, an activated TGF-β ligand will initiate the TGF-β signaling by binding these receptors. TGF-β can induce FoxP3 in human CD4+ CD25+ T cells and regulate the development of CD25+ regulatory T cells [190]. In normal cells, TGF-β blocks cell cycles at the G1 stage and stops proliferation and differentiation of cells and promotes apoptosis [191]. However, once an epithelial cell has been transformed into an adenocarcinoma, parts of TGF-β signaling are mutated, and subsequently TGF-β promotes tumor growth, migration, invasion, and metastasis at an advanced stage of CAC [192]. Recently, Becker’s group elegantly demonstrated that TGF-β receptor II-deficient mice developed an increased number of tumors as compared to WT mice. In contrast, TGF-β transgenic mice showed significantly less number of tumors as compared to WT. The authors concluded that TGF-β signaling in infiltrating T cells suppresses colon cancer progression by inhibiting IL-6 trans-signaling in tumor cells [159]. Overall, TGF-β seems to have a protective effect on chronic colitis and CAC development, at least in early stages [193].

Insulin-Like Growth Factor (IGF). IGFs are polypeptides, which show a high sequential homology to insulin. IGFs generate a complex system with two ligands (IGF-1 and IGF-2), two receptors (IGF1R and IGF2R), a family of six IGF-binding proteins (IGFBP 1–6), and associated IGFBP degrading enzymes [194, 195]. IGF1R activation leads to autophosphorylation of receptor and activation of signaling cascades including the GRB2/Ras/ERK and IRS-1/PI3K/AKT pathways [196]. Of note, IGF-2 is overexpressed in many solid tumors including colon cancer [197], and also loss of imprinting (LOI), an epigenetic alteration, of IGF-2 gene (IGF2) was discovered in many types of cancer including ovarian, lung, liver, and colon [198]. Approximately 10% of the population shows LOI of IGF2, and it seems to be associated with a personal and/or familial history of colorectal neoplasia since the variant showed a 5-fold increased frequency of colon cancer [199, 200]. Kaneda et al. reported that LOI and APC<sup>min</sup> double heterozygous mice have an enhanced sensitivity to IGF-2 signaling, and AOM-treatment in those mice showed a 60% increased number of premalignant aberrant crypt foci formation as compared to LOI(−) littermates [201]. These results strongly suggest that epigenetic alterations in IGF2 in normal cells may affect cancer risk by altering the balance of differentiated and undifferentiated cells [201].

As described above, IGFs and IGFRs have been highly implicated in cancer pathophysiology. It has been reported by some groups that IGF1R inhibition by administrating an antagonistic monoclonal antibody against IGF1R (designated EM164) [202] or selective kinase inhibitor [203] (designated NVP-ADW742) showed antiproliferative and/or proapoptotic effects in solid tumors, suggesting that selective IGF1R inhibitors should be one of the useful therapeutic strategies in treating cancers.

Endothelial Growth Factor (EGF). EGF is a low molecular weight (6 kDa) polypeptide, which plays a pivotal role in
cellular proliferation, differentiation, cell growth, and cell survival by binding with high affinity to its receptor EGFR on the cell surface and subsequently stimulates the intrinsic protein-tyrosine activity of EGFR [204–206]. On the basis of several clinical trials, EGF appears promising for the treatment of IBD. An approximate 80% remission rate has been demonstrated in left sided UC patients with daily EGF enemas for 2 weeks as compared to 8% in placebo group \( (P < .001) \) [207]. Rabamipide, an amino acid analogue of 2-(1H)-quinolinone, efficiently upregulates EGF and EGFR expression. A significant improvement was observed in the clinical and endoscopic findings with twice daily Rabamipide enemas, which were given to patients with UC proctitis for one month [110]. There is a big concern, however, that systemic use of EGF might have potent mitogenic effects by increasing tumor development and/or progression in APC Min mice [208]. EGFR signaling seems to be required for early stages of colonic carcinogenesis by upregulating cyclin D1 and Cox-2 expressions in microadenomas in AOM-induced cancer model [209]. EGF can form a complex with \( \beta \)-catenin, possibly through receptor tyrosine kinase-Pi3K/Akt pathway, and further activate Wnt signaling pathway [210]. As shown in Figure 3, cross-communication between Wnt- and EGFR-signaling pathways allows the integration of the diversity of stimuli in CECs and promotes tumor progression [210]. Furthermore, EGFR signaling augments the expression of epithelial CHI3L1 [211], which further promotes tumor angiogenesis and migration [212]. EGF signaling also upregulates the proliferation of aberrant crypt foci, which is the precursor to colon cancer [213]. In summary, EGF may be a useful therapeutic reagent for treating severe UC, but at the same time, it has a subsequent risk of malignant change in the early stage of colon cancer.

5.2.3. Calcium. Calcium is an essential dietary mineral, which is commonly included in milk products and dark green vegetables. It has been reported that a calcium enriched diet significantly reduces the number of total aberrant crypt foci in AOM-treated mice or rats [214]. Other reports utilizing animal models also support findings of calcium’s ability to inhibit colorectal cancer development [215, 216]. According to a report of the American Cancer Society’s Cancer Prevention Study II Nutrition Cohort, which recruited more than 120,000 examinees, men and women who had the highest intakes (approximately 1200 mg per day) of calcium showed a modestly reduced risk of colorectal cancer compared with those who had the lowest intakes of calcium [217]. Many other studies also report that individuals who had a modest to high calcium intake reduced their risk of cancer [218–220]. The exact mechanism of action of calcium is still unclear, but it binds to bile acids and fatty acids in the gastrointestinal tract to form insoluble complexes (calcium soaps). In addition, calcium may suppress cell proliferation in the lining of the colon or cause proliferating colon cells to undergo differentiation [221].

5.3. Chemokines. Chemokines are small chemotactic cytokines, and classified as 4 different types: CC-\( \sim \), CXC-\( \sim \), C-, and CX3C-chemokines. Chemokines bind to chemokine receptors, which are G protein-coupled receptors, and they are divided into four families: CXCR (bind CXC chemokines), CCR (bind CC chemokines), CX3CR1 (binds to CX3C), and XCR1 (binds to XC chemokines) [222]. Some chemokines have proinflammatory effects and efficiently promote migration of hematopoietic and nonhematopoietic cells to the site of infection or inflammation. In contrast, other chemokines keep tissue homeostasis during the normal process of tissue development. TNFα induces expression of several chemokines in colonic mucosal cells during the development of IBD [223]. TIR8 (also called as SIGIRR, a member of IL-1/TLR family) deficient mice cause severe colitis with cancer formation after AOM/DSS-induced colitis, and these mice showed significantly increased production of KC/CXC, MCP-1/CCL2, and MIP1α/CCL3 chemokines by tumor cells [224]. These chemokines enhance leukocyte infiltration and tumor growth/migration. In particular, CXC and MCP-1 chemokines are known for their effects in enhancing angiogenesis in colon cancer [225, 226]. Popivanova et al. also reported that MCP-1/CCL2 is a crucial mediator of colon cancer development since CCR2 (a specific receptor for MCP-1/CCL2) KO mice showed a milder form of colitis with less macrophage infiltration and a lower incidence of tumors with attenuated COX-2 expression in the AOM challenged model [134]. In contrast, MCP-1/CCL2-antagonist-treated mice showed reduced tumor incidence and size in the same animal model. These results strongly suggest that MCP-1/CCL2 may be a potential target in the treatment of colorectal carcinoma associated with chronic inflammation. Furthermore, D6 (a promiscuous decoy and receptor that scavenges inflammatory CC chemokines) plays a nonredundant role in suppressing inflammatory immune responses in various organs including lungs and skin [227]. D6 KO mice were more susceptible to chemically induced colitis, as compared to WT mice, and failed to recover from the colitis. They also exhibited a higher level of proinflammatory cytokine productions and increased number of tumor development in the distal part of colon [227]. In summary, CC-chemokines and their receptors are novel players in tumor promotion and progression during the course of chronic colitis.

5.4. Mammalian Chitinases. Chitin, a polymer of \( \beta \)-1,4-N-acetyl-glucosamine, is produced by various living organisms including insects, fungi, crustaceans, and many other organisms except mammals [228]. Chitin can be degraded by chitinases (EC 3.2.1.14) that belong to members of the glycohydrolase family 18, in which bacterial as well as plant chitinases are included [229]. Chitinases have been generally considered to lack in mammalian bodies due to the absence of chitin. However, recent studies have identified many chitinases including CHI3L1 [230], acidic mammalian chitinase [231], chitotriosidase [232], and Ym-1 [233] in mammals, and the expression of these chitinases is highly upregulated during the development of chronic inflammation conditions [25].

Serum levels of CHI3L1 are significantly elevated in patients with IBD [234] as well as those with colorectal
cancer [235], and the expression is positively associated with bad prognosis of these patients [236, 237]. CHI3L1 plays an important role in protecting cancer cells from undergoing apoptosis and also effects cellular invasion by strongly binding with heparin, collagens, and hyaluronic acid, all of these are important constituents of extracellular matrix [238, 239]. Recently, it has been reported that normal human bronchial epithelial cells express CHI3L1 under mechanical stress, which is driven by an EGFR and extracellular signal-regulated kinases (ERK)-1/2 signaling pathways. This result strongly suggests that direct activation of EGFR with ERK family ligands such as EGF and heparin-binding (HB) EGF induces CHI3L1 expression in epithelial cells [240]. Therefore, growth-stimulating effects of epithelial CHI3L1 in response to inflammatory or stressful stimuli seems to be a critical and physiological function in remodeling and maintaining the basic architecture of epithelium; however, overproduction of CHI3L1 from the epithelium must be a cue for further prolonged inflammation and for developing inflammation-associated carcinogenesis, ironically. Currently, exact biological function of CHI3L1 as well as other chitinases in CAC is still largely unknown. Further studies will help clarify the critical role of mammalian chitinases in chronic inflammation and the following carcinogenic change in epithelial cells, which will provide a rationale for the development of novel and new type of immunotherapy for improving the lives of patients with inflammation-associated carcinogenesis.

6. Conclusions

It has been strongly anticipated to improve the clinical course of IBD patients not only by creating new diagnostic and therapeutic approaches but also by preventing inflammation-associated cancer formation. Currently, a variety of genetically engineered or chemically induced animal models of CAC are available and are very useful for further analysis of the exact mechanisms underlying the pathogenesis of CAC. Through the animal models, we have learned that a limited number of inflammatory cytokines, chemokines, and growth factors play crucial roles in CAC development. Thus, effective and targeted anti-inflammatory therapies without adverse effects are warranted in order to prevent the development of CAC in IBD patients, and the animal models would help us with the invention of anti-inflammatory therapies by testing therapeutic strategies and reagents in preclinical settings.

Abbreviations

AOM: Azoxymethane
APC: Adenomatous polyposis coli
APC/C: Anaphase-promoting complex
BUB: Budding uninhibited by benzimidazoles
CAC: Colitis-associated cancer
CCL: Chemokine (C-C motif) ligand
CCR: Chemokine (C-C motif) receptor
CD: Crohn’s disease
CECs: Colonic epithelial cells
CHI3L1: Chitinase 3-like-1 (YKL-40)
COX-2: Cyclooxygenase-2
CTT: Cotton top tamarins
DMH: 1,2-dimethylhydrazine
EGF: Epidermal growth factor
ERK: Extracellular signal regulated kinases
FAP: Familial adenomatous polyposis
HNPPC: Hereditary nonpolyposis colorectal cancer
IBD: Inflammatory bowel disease
IFN: Interferone
IGF: Insulin-like growth factor
iNOS: Inducible nitric oxide synthesis
KO: Knockout
MAD: Mitotic arrest-deficient
MAM: Methyl azoxy methane
MCP: Monocyte-chemoattractant proteins
MIP: Macrophage inflammatory proteins
MSI: Microsatellite instability
NSAIDs: Nonsteroidal anti-inflammatory drugs
sPLA: Secretory phospholipase
TGF: Transforming growth factor
TLRs: Toll-like receptors
TNFRs: Tumor necrosis factor receptors
UC: Ulcerative colitis
WT: Wild type.

Acknowledgments

The authors are grateful to Dr. Atushi Mizoguchi for his helpful discussion and advice. The authors would like to thank Mr. Terry Danford Lott and Ms. Cindy W. Lau for their excellent assistance in preparing this paper. This work has been supported by National Institute of Health (DK 80070, DK74454, DK64289, and DK43351), and grants from the Eli and Edythe L. Broad Medical Foundation and American Gastroenterological Association Foundation to E. Mizoguchi. M. Kanneganti is a recipient of a Student Research Fellowship Award from the Crohn’s and Colitis Foundation of America Inc. in 2010.
