More than one-third of the world’s population is infected with one or more helminth parasites. Helminth infections are prevalent throughout tropical and subtropical regions where malaria pathogens are transmitted. Malaria is the most widespread and deadliest parasitic disease. The severity of the disease is strongly related to parasite density and the host’s immune responses. Furthermore, coinfections between both parasites occur frequently. However, little is known regarding how concomitant infection with helminths and Plasmodium affects the host’s immune response. Helminthic infections are frequently massive, chronic, and strong inducers of a Th2-type response. This implies that infection by such parasites could alter the host’s susceptibility to subsequent infections by Plasmodium. There are a number of reports on the interactions between helminths and Plasmodium; in some, the burden of Plasmodium parasites increased, but others reported a reduction in the parasite. This review focuses on explaining many of these discrepancies regarding helminth-Plasmodium coinfections in terms of the effects that helminths have on the immune system. In particular, it focuses on helminth-induced immunosuppression and the effects of cytokines controlling polarization toward the Th1 or Th2 arms of the immune response.

1. Introduction

Currently, it is estimated that approximately one-third of the almost three billion people who live on less than two US dollars per day are infected with one or more helminths [1]. Human infections with these organisms remain prevalent in countries where the malaria parasite is also endemic [2]. Consequently, coinfections with both parasites occur frequently [3, 4]. These interactions could have potential fitness implications for both the host (morbidity and/or mortality) and the parasite (transmission). Several studies have shown that the ability of a parasite to successfully establish an infection will depend on the initial immune response of the exposed host [5, 6]. When entering the host, a parasite will experience an “immune environment” potentially determined by both previous and current infections [7–9]. It is widely recognized that, in the presence of Th2 effector response, Th1 response is suppressed and vice versa [10]. Thus, Th2-type response evoked in response to helminth infection would in theory have the ability to suppress proinflammatory Th1 response that generates immunopathology in Plasmodium infection.

Despite the fact that helminth parasites cause widespread, persistent human infection that results in a Th2 immune response, the influence of helminths on the duration of episodes of malaria in humans is not clear. The questions of how the coexistence of helminths and Plasmodium parasites within the same host might influence the immunological responses to each species and whether interactions affect resistance, susceptibility, and the clinical outcome of malaria has yet to be answered.

In this review, we attempt to answer these questions and particularly address whether the preexistence of a Th2/T regulatory response induced by helminths could affect the immune response against Plasmodium.
Before analyzing the influence of helminth infection on malaria, we must first briefly outline the immune response to Plasmodium infection and later outline the immune response to helminths parasites, as this is important to subsequent analyses of how malaria can be modified by the helminths.

2. Plasmodium

Malaria is caused by protozoan parasites belonging to the genus Plasmodium; it is transmitted by female Anopheles mosquitoes. Plasmodium is still one of the most successful pathogens in the world and is a major cause of morbidity and mortality in tropical countries. Five species of Plasmodium (i.e., P. falciparum, P. vivax, P. malariae, P. ovale, and P. knowlesi) are responsible for all human infections [11, 12].

Plasmodium parasites have a complicated, multistage life-cycle involving an Anopheles mosquito vector and a vertebrate host. The parasite develops in two stages in its human host: in the liver (the exoerythrocytic stage) and in the blood (the intraerythrocytic stage). The most characteristic features of malaria in humans are a fever that occurs every 48 to 72 h depending on the species of Plasmodium, chills, headache, and gastrointestinal symptoms. In a naive, untreated individual, these can rapidly escalate into cerebral malaria (CM), anemia, severe organ failure, and death [13].

2.1. Immune Response during Plasmodium Infection. The immune response to Plasmodium is poorly understood; it depends on the parasite species and the specific stage within the host [12]. In addition, it is dichotomized into the preerythrocytic response, which is directed against the sporozoite and liver-stage parasites, and the blood stage response, which is directed against merozoites and intraerythrocytic parasites.

Although animal models do not fully replicate human malaria, they are invaluable tools for elucidating immune processes that can cause pathology and death [14]. Several mouse strains have been used to study the immune response to different combinations of Plasmodium species, such as P. berghei [15–20], P. yoelii [15, 21–24], P. chabaudi [25–30], and P. vinckei [31] (Table 1). These malarial models suggest that the efficiency of parasite control requires both a humoral and a cellular immune response, most likely in cooperation, although the importance of each is not entirely clear. For example, immunity to the sporozoite depends on antibodies to surface proteins, such as CSP-2 [32, 33] and liver-stage antigen (LSA-1) [34]; these antigens induce the production of antibodies that neutralize or block the invasion of hepatocytes [35]. Once sporozoites have entered the hepatocyte, the parasite clearance in mice requires CD8+ T cells [36], natural killer cells (NK), and NKT and yδ T cells that produce IFN-γ to eliminate infected hepatocytes [35]. When the parasite invades red blood cells (RBC), it dramatically alters the physiological and biochemical processes of its host cell. Parasite-infected RBCs (pRBC) express parasite-encoded molecules on their surface that affects the RBCs’ mobility and trafficking within the body. The parasite biomass increases very rapidly and activates innate immune mechanisms, including NK cells and yδ T cells [13].

NK cells play an important role in restricting parasite replication. The absence of NK cells is associated with low IFN-γ serum levels and increased parasitemia in mice infected with P. chabaudi [37]. Likewise, the absence of IFN-γ reduces the ability of mice to control and eliminate parasites, eventually resulting in the death of the animals [38, 39]. Interestingly, macrophages (Mφ), but not IFN-γ, play a major role in the control of early peaks in lethal infections with P. yoelii [40]. In addition, IFN-γ produced by CD4+ T cells plays a pivotal role in protective immunity against non-lethal strains of Plasmodium [41, 42]. In contrast, the infection with P. berghei ANKA induces high levels of IFN-γ and TNF-α which are associated with cerebral malaria [43]. However, the peak of parasitemia in athymic mice tends to be similar to the peak in WT mice. These results suggest that extrathymic T cells are the major lymphocyte subset associated with protection against malaria [44].

In a resistant strain of mice, the presence of the parasite induces the production of proinflammatory cytokines, such as IL-1β, IL-6, TNF-α, and IFN-γ. Furthermore, IL-12 is also necessary for elimination of P. chabaudi AS [45], P. berghei XAT [20], and P. yoelii XNL [46].

Besides, the inflammatory cytokine MIF (macrophage migration inhibitory factor) induces pathogenesis and susceptibility on BALB/c mice infected with P. chabaudi, high serum levels of MIF correlated with severity of disease [47]. In addition, infection of MIF knockout mice with P. chabaudi increases survival [48].

CD4+ T cells, together with B cells, are crucial to develop efficient protection in murine experimental models [49, 50]. Whereas IFN-γ, produced by TCD4+, activates Mφ-mediated responses [51], the antibodies produced by B cells inhibit invasion of RBCs by the parasites [52], opsonize parasitized RBCs, block PRBC adhesion to the vascular endothelium, and neutralize parasite toxins [35]. In addition, mice rendered B cell deficient by treatment with anti-μ antibodies or B cell knockout mice (μMT) are unable to clear the erythrocytic infection of P. chabaudi [50, 53, 54]. Specifically, the early acute infection is controlled to some extent, giving rise to chronic relapsing parasitemia that cannot be cleared. Finally, parasitemia can be reduced by adoptive transfer of B cells [50].

Antibodies also induce pathology due to parasite antigens that are freed and adhere to healthy erythrocytes; this generates anemia or autoimmune reactions that cause damage to the kidneys and other tissues [55–58]. For example, pathogenesis of malaria nephropathy is linked to subendothelial deposits of immune complexes containing IgG and IgM [59, 60]. The antibodies involved in the elimination of the parasite mainly belong to cytophilic subclasses (IgG1 and IgG3) [50, 61]. In addition, high levels of immunoglobulin E (IgE) correlate with protection against severe malaria [62–64].

Interestingly, after the peak of parasitemia, cellular immune responses should switch from Th1- to Th2-type response in P. chabaudi infected mice [65], because the malaria pathogenesis is caused by inappropriate or excessive inflammatory responses to eliminate the parasite [43, 66].

Interestingly, *Plasmodium* can modulate the response of antigen presenting cells, such as Mφ and dendritic cells (DC), which leads to suppression of the immune response [67]. In the infection with *P. yoelii* YM, the DC function is affected by the presence of TNF-α [68]. Wykes et al. suggested that damage to the activity of DCs is due to a virulence factor that is present in certain parasite strains because, when DCs were transferred from mice infected with a “nonlethal” strain to mice infected with a "lethal" parasite strain, the mice were protected [46].

The regulatory T cells are extremely important to control the inflammatory process in malaria, the number of CD4⁺ CD25⁺ Foxp3⁺ regulatory T cells (Treg) increases in mice infected with *P. yoelii* [69] or *P. berghei* [70]. In addition, mice infected with the lethal *P. yoelii* XL17 show higher levels of IL-10 and TGF-β compared to mice infected with the nonlethal strain *P. yoelii* XNL, at early time points during infection [71]. Furthermore, the suppression of T cells induces lethality in mice infected with *P. yoelii*, while neutralization of TGF-β and IL-10 decreases parasitemia and prolongs the survival of infected mice [71, 72]. Accordingly, Couper et al. reported that the main sources of IL-10 in lethal infection with *P. yoelii* are Treg cells [73]. Finally, the ablation of Treg cells from *P. yoelii*-infected DEREG-BALB/c mice significantly increases T cell activation and decreases parasitemia [74]. In addition, in mice infected with nonlethal strains of *P. yoelii*, the presence of cytokines such as IL-10 and TGF-β during the chronic phase of infection was detected [71]. Thus, these data together suggest that the outcome of malaria infection could be determined by the balance of proinflammatory and regulatory immune responses, which could inhibit pathology (Figure 1).

3. Helminths

Helminths are multicellular worms, some of which have adapted successfully to a parasitic lifestyle. They can be classified into three taxonomic groups: cestodes (e.g., *Taenia solium*), nematodes (e.g., *Ascaris lumbricoides*), and trematodes (e.g., *Schistosoma mansoni*). Helminths vary in their biology in terms of size, lifecycle, and the diseases they cause. However, despite this complexity, helminths usually cause asymptomatic and chronic infections [76]. Helminths are among the most widespread infectious agents in human populations, especially in developing countries; they affect more than a third of the world’s population, and more than 20 species infect humans (Table 2) [1, 77–83].

3.1. Immune Response during Helminth Infections. Infection of mammals by helminth parasites typically results in a conserved series of immune events that are orchestrated and dominated by T helper cell type (Th2) events, characterized by the activation of eosinophils, basophils, and mast cells; high levels of immunoglobulin E (IgE); and the proliferation of T cells that secrete IL-4, IL-5, IL-9, and IL-13 [84, 85]. Despite this response, helminths are able to modulate and suppress the host immune response to promote their own survival and their persistence in the host for a long time, resulting in chronic infection [76, 86, 87]. These mechanisms include the ability to induce regulatory responses via regulatory T cells (Treg) which express molecules that inhibit the immune response, such as glucocorticoid-induced TNFR-related protein (GITR) and the receptor cytotoxic T lymphocyte antigen 4 (CTLA-4) [88–91]. Treg cells also secrete suppressive cytokines, such as IL-10 and TGF-β [92]. On the other hand, B regulatory cells (Breg) also contribute to immune modulation and can release IL-10 and restrict proinflammatory responses [93]. Helminths also induce the differentiation of anti-inflammatory Mφ, called alternatively activated Mφ (AAMφ) [94, 95], as well as regulatory dendritic cells (DCreg), which are characterized by the expression of the regulatory cytokines IL-10 and TGF-β [96, 97] (Figure 2).

This anti-inflammatory or regulatory response could be potentially detrimental to the host if it interferes with the development of protection against other infections that require an inflammatory response, such as *Leishmania major* [9, 98] or *Trypanosoma cruzi* [8].

The hyporesponsive immune response induced during chronic helminth infection affects not only the response to helminth antigens but also to other antigens. Several studies have examined the effect of infections on the immune response to other unrelated antigens. In particular, it has been

Figure 2: Helminth infections are strong inducers of a Th2-type immune response. These infections are characterized by the expansion and activation of eosinophils, basophils, and mast cells (1). Their upregulation due to high levels of immunoglobulin E (IgE) and the proliferation of T cells that secrete IL-4, IL-5, IL-9, and IL-13 are part of the host immune response against the parasite (2). However, helminth infections tend to be long-lived and largely asymptomatic because helminth infections are sustained through a parasite-induced immunomodulatory network, in particular through activation of regulatory T cells (3) and systemically elevated levels of IL-10 produced by B regulatory cells (4). They are additionally affected by the expression of the regulatory cytokines IL-10 and TGF-β, produced by regulatory dendritic cells (5) and alternatively activated Mφ (AAMφ) (6).
shown that the response to vaccines can be modified by the presence of concomitant helminth infection. For example, chronic *Onchocerca* infection [99], *Lymphatic filariasis* [42], or *Schistosoma* [100] reduces the effectiveness of the tetanus vaccine. Likewise, chronic *Onchocerca* infection affects *Bacillus Calmette-Guérin* and *Rubella* vaccinations [101]. Similarly, *Ascaris lumbricoides* reduces the response to the oral cholera vaccine, which can be restored by albendazole treatment [102]. However, helminthic infections are beneficial in the control of excessive inflammatory reactions, such as Crohn’s disease [103] and ulcerative colitis [104], as well as in allergic diseases [105–107] and autoimmune diseases, such as encephalomyelitis [108, 109] and arthritis [110].

Despite the widespread acceptance that helminthic infections influence each other directly or indirectly, little attention has been paid to helminth-*Plasmodium* coinfections. One reason is that the interactions involved are complex and difficult to understand. Here, we will try to discuss several reports about helminth-malaria coinfections to clarify the consequences of this interaction.

### 4. Human *Plasmodium*-Helminth Coinfection

*Plasmodium* spp. infect between 349 and 552 million people and kill over one million each year; approximately 40% of the world’s population is at risk of being infected [2, 111]. Importantly, people living in malaria-endemic regions are exposed to other pathogens, especially those associated with poverty, such as helminths.

Several studies have been carried out to explore the influence of helminths on *Plasmodium* infection in humans (Table 3). However, the evidence described in these researches are controversial. While some studies have reported that helminth infection favors protection because reduces the *Plasmodium* parasite density [112], promotes protection against clinical malaria [113, 114], reduces anemia [113, 115, 116], cerebral malaria [117] and renal failure [118] (Table 3(a)). Other studies showed no influence of helminths on the cure of *Plasmodium* infection [119–121] (Table 3(b)). In contrast, others showed an increased susceptibility to *Plasmodium* infection [114, 122], increased risk of complications [123–125], anemia [125, 126], hepatosplenomegaly [127, 128], and increased *Plasmodium* parasite load [129, 130] (Table 3(c)).

Although a Th2 phenotype is a conserved response to helminth infection in human and mice, the nature of the host immune response varies considerably between species of helminths; in some cases Th1 immune response predominates, depending on both the time of infection and the helminth development stage [131, 132]. The time that Th1 immune response is sustained until it polarizes toward Th2, could vary between species [133–135]. Thus, the controversial results related to helminth-*Plasmodium* coinfection in humans could be explained because many studies did not consider critical features of the helminth parasite biology. For example, the biological niche or parasite stage within the host. Neither the previous time of infection with the helminth nor the nutrition state and age of the host were taken into account.

Because all of these variables were not considered in existing studies in humans and in order to establish a possible consensus, we review in detail the murine *Plasmodium-helminth* coinfections, which in theory, controlled variables more rigorously.

### 5. Experimental Models of Coinfection

Although helminth infections in mice are a questionable model for chronic helminth infections in humans, the fact is that many intraintestinal helminths can reach large biomass which can change the cytokine environment and therefore the possible mechanisms of response. By establishing chronic infections and inducing strong Th2-type responses, helminths could have a potentially significant influence on the nature of the immune response in infected individuals and hence modify their susceptibility to subsequent infections with other important pathogens, at least those that require a Th1-type or mixed Th1-/Th2-type immune response, such as *Plasmodium* sp.

#### 5.1. *Schistosoma*-Plasmodium Coinfection

According to the theory that Th2-type response evoked in response to helminth infection would have the ability to suppress proinflammatory Th1 response that generates immunopathology in *Plasmodium*-infected individuals, there are some reports of experimental models of coinfection with *Plasmodium berghei ANKA* (*Pb*) after *Schistosoma mansoni* (*Sm*) infection in ICR mice or with *Schistosoma japonicum*- (*Sj*) *Pb* in C57BL/6 mice 7 or 8 weeks after helminthic infection, respectively; both coinfections showed a delay in death of mice [136, 137]. Interestingly, there was a reduction in the brain pathology associated with high levels of the anti-inflammatory cytokines II-5, IL-10, and IL-13 [136–138].

In contrast, similar coinfection with *Pb* 7 or 8 weeks after *Sm* infection showed an increase in mortality and parasitemia in Swiss albino and C57BL/6 mice [138, 139]. Moreover, the coinfections in Swiss albino mice reduced the effectiveness of antimalarial treatments and delayed elimination of the parasite [139] (Table 4(a)). In these reports neither evidence of immune response nor pathology data were shown. Thus, we speculate that increase parasite load was probably due to the presence of helminth than inhibited Th1-type immune response which was able to contain the replication of *Plasmodium*, and the increased mortality was due to parasite load rather than a pathological Th1-state dependent. In line with this hypothesis, coinfection with *Plasmodium chabaudi* (*Pc*) at 8 weeks after *Sm* infection in C57BL/6 mice allowed high *Pc* replication. This increase was associated with low levels of the proinflammatory TNF-α [140].

It is known that the immune response against *Schistosoma* shifts from an early helminth-protective Th1-type immune response to a late helminth-permissive Th2-type response during the course of infection [134]. Thus, the moment when the second infection is acquired (2, 4 and 6 weeks post-helminth infection) would be critical for disease outcome and pathology [141]. These findings could be supported by the fact that chronically *Sm*-infected BALB/c mice coinfected (6 weeks) with the nonlethal strain *Plasmodium yoelii* N XL...

(PyNXL) showed high mortality. In contrast, no mortality was observed in acutely (2 or 4 weeks) coinfected mice, although they developed high parasitemia and hepatomegaly, was higher in coinfected mice compared with mice infected with each parasite separately [141] (Table 3(a)). Therefore, the time of previous infection may influence the response against Plasmodium.

Together, these reports suggested that the Th2 response, induced by Schistosoma, plays an important role in protecting against immunopathology in cerebral malaria. However, the presence of Schistosoma does not appear to modify the virulence of Pb and, consequently, it does not alter the lethality of Plasmodium infection.

Finally, one report scape to the theory that Th2-type immune response evoked by the helminthic infection would possess the ability to suppress the proinflammatory Th1-type response in its host. Sm-infected A/J mice coinfected at 8 weeks with Pc were protected by the presence of concomitant Sm infection. The mice escaped death due to malaria; this effect was accompanied by enhanced levels of IFN-γ [142] (Table 4(a)).

5.2. Heligmosomoides polygyrus-Plasmodium Coinfection. Several studies used mice of the same genetic background. Additionally, equivalent helminth and Plasmodium strains have been used to explain whether previous helminthic infection plays an important role in the immune response against Plasmodium. Su et al. showed that C57BL/6 mice previously infected with Heligmosomoides polygyrus (Hp) and challenged with Pc either 3 or 5 weeks after helminthic infections developed high Pc-parasitemia and mortality, which was associated with low levels of IFN-γ and high levels of TGF-β and IL-10 [143]. However, Hp-Pc coinfection at 2 weeks resulted in less severe pathology (i.e., less hypothermia and hypoglycemia) and induced earlier reticulocytosis compared with mice infected only with Pc [144] (Table 4(b)).

Helmby in 2009 showed that mice developed high mortality in the Hp-Pc model when the two infections were introduced simultaneously. The mortality was due to severe liver pathology associated with increased IFN-γ, IL-17, and IL-22. Interestingly, when using an IFN-γ and IL-23 knockout strain, the mice survived the coinfection [145]. Thus, simultaneous Hp-Pc coinfection increased mortality, which may be a consequence of a synergistic effect that increased the inflammatory response (Table 4(b)).

In fact, in the first case, in which Hp-Pc coinfection was performed at 3 or 5 weeks after the initial helminthic infection, the high mortality observed may have been due to the anti-inflammatory response generated by the previous helminthic infection, which inhibited the inflammatory response necessary for control of the Plasmodium infection. However, when the coinfection was performed at the same time, mice developed a stronger inflammatory response, which generated greater pathology and mortality. This susceptibility is supported by the observation that chronic helminthic infection suppresses effective vaccine-induced protection against Plasmodium. However, when mice were administered with antihelminthic Hp treatment before malaria vaccination, the protective immunity against Pc was restored [146]. Therefore, the timing of the infection with Hp plays an important role in the type of immune response that is generated within the host, and it determines the susceptibility following challenge with Plasmodium.

The genetic background of mice infected with helminths has a crucial role in the outcome of the immune response to Plasmodium. For example, coinfection with the nonlethal PyNXL strain at 2 weeks after Hp infection in C57BL/6 mice resulted in exacerbated pathology and poor survival of mice. This susceptibility was associated with a reduced response against PyNXL (i.e., low levels of IFN-γ) in the spleen cells. As a consequence, it increased the activation of Treg cells [147]. However, the same coinfection at 3 weeks in BALB/c mice decreased the pathology associated with low levels of IFN-γ and increased levels of IL-4, but not IL-10 [148]. Therefore, the genetic background of mice infected with the helminth determines the outcome of PyNXL infection (Table 4(b)).

What happens when a lethal strain of Plasmodium was used in coinfection with Hp? The Pb ANKA infection in C57BL/6 mice induced typical symptoms of ECM [160, 161]. Coinfection with Hp-Pb ANKA 2 weeks after initial helminthic infection did not modify the development of ECM despite accelerated Pb growth in vivo [149]. Likewise, other results from the same model of coinfection in BALB/c and C57BL/6 mice showed no differences in parasitemia, anemia, or body weight in relation to mice infected only with Plasmodium [150]. Therefore, Hp infection does not affect the outcome of Pb ANKA (Table 4(b)).

5.3. Echinostoma caproni-Plasmodium Coinfection. Studies in BALB/c mice infected for 3 weeks with E. caproni (Ec) and then coinfected with the nonlethal strain PyNXL showed that exacerbation of Plasmodium-induced pathology was associated with a deficit in IFN-γ production [148]. Similarly, when Ec-infected mice were coinfected at 5 weeks, increased mortality was observed. The exacerbated pathology was reversible through the clearance of Ec worms via praziquantel treatment [151]. However, coinfection at 5 weeks with the lethal PyXL strain did not alter the course of infection; all mice infected with PyXL (i.e., alone, in combination with E. caproni, or praziquantel treated) died on day 10 after infection [151] (Table 4(c)). Therefore, Ec infection does not affect the outcome of lethal PyXL, but Ec infection affects the protective response against a nonlethal Plasmodium strain.

5.4. Strongyloides ratti-Plasmodium Coinfection. Murine Strongyloides ratti (Sr) infection is a transient helminthic infection that is resolved spontaneously within 3-4 weeks. This infection induces a strong Th2-type immune response at day 6 after infection [135]. When BALB/c mice were coinfected with the nonlethal strain PyNXL at day 6 after Sr infection, Sr induced a slightly enhanced peak of Plasmodium parasitemia and loss of body weight. In contrast, in C57BL/6 mice coinfected at day 6, parasitemia level and body weight were not altered. Interestingly, the Th2-type immune response induced by Sr was significantly reduced upon PyNXL coinfection [152]. In addition, PyNXL clearance was not affected by previous infection with Sr in either C57BL/6 or BALB/c mice. Moreover, infection with Sr in BALB/c
mice did not change the efficacy of vaccination against *Pb ANKA* [153]. Therefore, infection with *Sr* does not affect the protective response against *Plasmodium*, although it generates small changes in parasitemia levels; which is not decisive for the outcome of *Plasmodium* infection (Table 4(d)).

5.5. *Nippostrongylus brasiliensis*-*Plasmodium* Coinfection. BALB/c mice infected with *Nippostrongylus brasiliensis* (*Nb*) exhibit a strong Th2-type immune response [162]. Even so, when BALB/c mice were coinfected with *Nb* and *Pc* simultaneously, the Th2 response against *Nb* was impaired by *Plasmodium*. Interestingly, the *Nb-Pc* coinfected had a beneficial effect; it slightly ameliorated the severity of malarial anemia (SMA) and decreased parasitemia levels [154]. Similarly, C57BL/6 mice infected for 3 weeks with *Nb* and then coinfect with *Pb* showed a delayed peak parasitemia and an increased survival time [155]. Thus, the presence of concomitant *Nb* infection plays an important role in inhibiting pathology associated with a challenge with *Pc* or *Pb* (Table 4(e)).

5.6. Coinfection with Other Helminths. Experimental models of coinfection with *Litomosoides sigmodontis* (*Ls*) 8 weeks and *Pc* infection in BALB/c mice showed increased SMA and weight loss associated with increased levels of IFN-γ [156]. In contrast, coinfection with *Ls* 8 weeks and *Pb* infection in C57BL/6 mice showed significantly reduced ECM rates associated with increased levels of IL-10. This protection was inhibited in IL-10 KO mice [157]. High levels of IL-10 were important in reducing pathology but also interfered with the protective response to *Plasmodium* in the liver. In particular, chronic infection with *Ls* interfered with the protective efficacy of a vaccine against sporozoite *Pb* in the liver [153]. Therefore, infection with *Ls* exacerbates the pathology of a *Pc* infection. In contrast, infection with *Ls* inhibits pathology in *Pb* infection due to an anti-inflammatory cytokine response ('Table 4(f)).

In addition, CBA/J mice infected with *Brugia pahangi* (*Bp*) for 1 week and then coinfected with *Pb* displayed a low mortality rate, and mice were protected against the development of ECM. This protection was associated with increased serum IgE levels and Th2 cytokine production [158] (Table 4(g)). Similarly, infection with *Trichinella spiralis* (*Ts*) for 1 or 4 weeks in C57BL/6 mice greatly enhanced their resistance against the fatal coinfection with *Pb* [159]. Therefore, these observations suggest that the Th2-type immune response reduces brain pathology and increases survival in *Bp*- or *Ts-Pb* coinfection, perhaps due to the anti-inflammatory environment generated by the previous helminth infection (Table 4(h)).

The studies described above lead to different conclusions, while some of them suggest that prior infection with helminths induces resistance to *Plasmodium* [136, 137, 142, 148, 154, 155, 157–159], other studies do not show effects [149–153] and finally some others demonstrated an increased susceptibility to *Plasmodium* infection [138–141, 143–148, 151, 153, 156]. These contrasting results may partially be explained because this interaction is affected by the timing between the hosts’ exposure to the helminth and *Plasmodium*. In addition, the strain of each parasite is also important, coinfection with nonlethal *Plasmodium* strains in the early stages of a helminthic infection delayed the onset of parasitemia due to early, specific high production of IFN-γ, but this response increased pathology. In contrast, a significant increase in susceptibility to nonlethal *Plasmodium* was observed when mice were coinfected with *Plasmodium* in the late stages of helminthic infection, when the Th2-type immune response is predominant.

Coinfection with lethal strains of *Plasmodium* in the late stages of a helminthic infection inhibits severe pathology and increases the survival of mice due to a decrease inflammatory response (mainly IFN-γ and TNF-α). In addition, the presence of a late anti-inflammatory Th2-type immune response induced by helminthic infection extended the survival of mice susceptible to *Plasmodium* infection; this may be due to a reduced pathological Th1-type immune response or may be due to induction of protective mix of Th1 and Th2 immune response. Recruitment and activation of Mφ are essential for the clearance of malaria infections, but these have also been associated with adverse clinical outcomes [163]. Specifically, immunopathology of severe malaria is often originated from an excessive inflammatory Th1-type immune response. The expansion of Treg cells and the alternative activation of Mφ by helminthic infections may modulate the excessive inflammatory response to *Plasmodium*. Therefore, the chronic helminth infections inhibited pathology and increased survival in the challenge with lethal strains of *Plasmodium*.

6. Conclusions

The findings in this review demonstrate that the immune environment generated by a previous helminthic infection influences the response against *Plasmodium*. A helminth that persists in its host is able to significantly modify the host’s susceptibility to or protection from *Plasmodium*. These modifications are dependent on the genetic background of mice, the type of helminth, and the time-course of the initial helminthic infection, which is crucial to the resulting immune response to *Plasmodium*.

The impact of helminth-*Plasmodium* coinfection on acute helminthic infection increased or synergized the Th1-type immune response. This might be successful in inducing a response that inhibits *Plasmodium* replication, but it increases the pathology and mortality in the host. Alternatively, chronically helminth-infected mice showed a shift toward Th2-type immune responses. This could render the host more susceptible to *Plasmodium* infection and favor their replication; however, this response protected the host from severe malaria (Figure 3). Overall, these results suggest that malarial immunity is influenced by helminthic infections. Therefore, the study and manipulation of antimalarial immunity seems difficult in the absence of any information concerning the effects of helminths on this response.

7. Perspectives

The helminth-*Plasmodium* interaction may have undesirable implications for global public health; for example, malaria
vaccines trials do not consider the immune response to helminths, and this could result in decreased performance or cause adverse effects. Thus, a better understanding of helminth-induced regulation in the antimalarial response is indispensable for the rational development of effective antimalarial vaccines and novel therapies to alleviate or prevent the symptoms of severe malaria. The risk that entire populations may have an increased susceptibility to *Plasmodium* should invite study regarding the possible epidemiological relevance of helminth infections and the impact of controlling them on malaria incidence. The presence of helminth infections could represent a much more important challenge for public health than previously recognized. Therefore, we would emphasize that it is extremely important to carry out experiments in animal models that use more rigorous criteria to define exhaustively all the ramifications of immune regulation and potential side effects of helminth infection in the context of malaria. These results would allow extrapolate the observation in human populations presenting malaria.
