Background. Methylenetetrahydrofolate reductase (MTHFR) SNP rs1801133 has been frequently investigated in recent years. Relevant candidate gene association studies with this SNP and osteonecrosis of the femoral head (ONFH) reported conflicting results. Meta-analysis provides a method to combine these data and to determine the association in a larger sample size. **Method.** We conducted a systematic search to identify possible studies. Four pooled ORs (odds ratios, T versus C, TT versus CC, TT/CT versus CC, and TT versus CT/CC), along with 95% confidence interval (CI), were calculated to evaluate the association between SNP rs1801133 and ONFH susceptibility. Both fixed effects model and random effects model were used. **Findings.** We eventually included twelve studies in this analysis, with results showing no overall association between ONFH susceptibility and SNP rs1801133 (T versus C: OR = 1.15, 95% CI = 0.97–1.38; TT versus CC: OR = 1.15, 95% CI = 0.91–1.46; TT/CT versus CC: OR = 1.09, 95% CI = 0.95–1.25; and TT versus CT/CC: OR = 1.16, 95% CI = 0.93–1.45). When stratified based on ethnicity, the results were still not significant. **Conclusion.** Our findings are generally supportive of no association between MTHFR SNP rs1801133 and the etiology of ONFH.

1. Introduction

Osteonecrosis of the femoral head (ONFH) is a painful disorder of the hip and features necrosis of femoral subchondral bone [1]. This disease is often observed in young adults and is frequently progressive. ONFH will often evolve into subchondral bone fracture, femoral head collapse, and subsequent hip joint degeneration, leading to poor long term outcomes [2]. The collapse of femoral head often leads to loss of function [3–5]. The pathophysiology of ONFH remains incompletely elucidated; intravascular coagulation may represent a pathogenetic mechanism resulting in bone ischemia and death [6]. Coagulation abnormalities in patients with

hip osteonecrosis are associated with an increase in risk of developing bone necrosis by predisposing thromboembolic phenomena [7].

A large number of outstanding researchers have identified multiple factors that genetically contribute to hypercoagulability and osteonecrosis, including protein C and protein S deficiency, factor V Leiden, prothrombin G20210A mutation, and higher lipoprotein levels [8–10]. In recent studies, several gene single nucleotide polymorphisms (SNPs) associated with thrombophilia have been implicated in ONFH [11]. Methylenetetrahydrofolate reductase (MTHFR) is an enzyme which plays a key role in the remethylation of homocysteine. A C→T mutation at nucleotide 677 leading to a valine

substitution for an alanine (677C > T, rs1801133) is reported to be functionally relevant to MTHFR enzymatic activation, homocysteine levels, and thrombotic events [12, 13].

Extensive research into the etiology of ONFH to date has focused on SNP rs1801133. Results of a study by Glueck et al. in 2001 showed that SNP rs1801133 was a genetic risk factor predisposing susceptibility to ONFH [14]. Recently, Li et al. investigated the association of the SNP with risk of ONFH in a sample of Chinese patients, finding supportive evidence of a significant association as well [15]. However, most replication studies reported that SNP rs1801133 is not a risk factor for the bone disease [16–18]. Hence, we hypothesize that the ONFH susceptibility risks may not be attributable to SNP rs1801133. In an effort to test this hypothesis, we performed a meta-analysis to combine all published data and to determine the association in a larger sample size.

2. Methods

2.1. Study Search and Selection. A systematic search of the PubMed (<http://www.ncbi.nlm.nih.gov/sites/entrez/>) and CNKI (<http://www.cnki.net/>) electronic database was conducted up to October 1, 2013, to identify all studies investigating the association between SNP rs1801133 and ONFH risk. “Osteonecrosis of the femoral head,” “ONFH,” “Methylenetetrahydrofolate reductase,” “MTHFR,” and “polymorphism” were the keywords we used in the search. The electronic search was complemented with a manual search of citations of all original articles.

There were three inclusion criteria for the meta-analysis. First, the study must investigate the association between SNP rs1801133 and ONFH risk by comparing ONFH patients with healthy or ONFH-free control subjects. Second, the study had to provide detailed genotype frequency or contain sufficient data with which we could calculate the frequencies of TT, CT, and TT. Third, the subjects must be humans and cannot be repeatedly used; if they were, we included the study with the largest number of subjects.

2.2. Data Extraction. Using the inclusion criteria listed above, two investigators picked out all eligible studies and extracted the following data from each of them: authors, year of publication, country of study, ethnicity, genotyping method, genotypic frequencies, and type of controls. Disagreements were resolved by discussion.

2.3. Statistical Analysis. We first checked the deviation from Hardy-Weinberg equilibrium (HWE) in control subjects using a chi-squared goodness-of-fit test. To evaluate the strength of the genetic association, four pooled ORs (odds ratios, T versus C, TT versus CC, TT/CT versus CC, and TT versus CT/CC) were calculated, along with the 95% confidence intervals (CIs). A statistical test described by Cochran was conducted to measure heterogeneity between studies [19]. In case of absence of heterogeneity, the pooled ORs were calculated assuming a fixed effects model [20], or a random effects model was used [21]. To identify if included studies influenced summary estimates substantially,

we performed sensitivity analysis by omitting one study at a time. Publication bias was qualitatively assessed using the funnel plots and Egger’s test [22]. All statistical tests were performed with the software Stata version 12.0 (Stata Corporation, College station, TX, USA). P value <0.05 was considered as significant.

3. Results

3.1. Extraction Process and Study Characteristics. Figure 1 summarizes the process of study identification. We yielded a total of 331 relevant articles (PubMed, 207; CNKI, 124). Evaluation of title, abstract, and full-text led to 12 eligible studies [14–18, 23–29]. General characteristics of the included studies are summarized in Table 1. Seven studies investigated the association of SNP rs1801133 with ONFH susceptibility in a sample of Caucasian population and five in Asian populations. Seven studies used healthy control subjects and four used ONFH-free subjects, with one not reporting such information. Most studies used polymerase chain reaction-restriction fragment length polymorphism (PCR-RFLP) to genotype SNP rs1801133. Deviation from HWE was tested in three studies [15, 16, 26].

3.2. Meta-Analysis Results. As shown in Table 2, all of the genetic models we tested showed that individuals with T allele appeared to be at higher risk of ONFH (T versus C: OR = 1.15, 95% CI = 0.97–1.38; TT versus CC: OR = 1.15, 95% CI = 0.91–1.46; TT/CT versus CC: OR = 1.09, 95% CI = 0.95–1.25; and TT versus CT/CC: OR = 1.16, 95% CI = 0.93–1.45) (Figure 2), although this was not statistically significant. In terms of stratified analysis by ethnicity, the results for both Caucasian and Asian populations were similar to those for the overall population (Table 2 and Figure 2).

3.3. Heterogeneity Test and Sensitivity Analyses. We observed no significant heterogeneity for SNP rs1801133 under all genetic models with the exception of T versus C ($P_{\text{Heterogeneity}} = 0.027$) (Table 2). Sensitivity analyses were conducted, and it was identified that Li et al. [15] and Kutlar et al. [16] were the main sources of heterogeneity, exclusion of which effectively increased homogeneity without significantly influencing the estimates of overall ONFH risk ($P_{\text{Heterogeneity}} = 0.223$, OR = 1.03, 95% CI = 0.92–1.17). This outcome assured the stability and reliability of our results.

3.4. Publication Bias. We evaluated the publication bias using the tests described by Begg and Egger. The shape of all funnel plots was symmetrical ($P > 0.05$). Begg’s test also showed that there was little publication bias across studies ($P > 0.05$) (Figure 3 for TT/CT versus CC).

4. Discussion

SNPs represent the most common type of DNA variation in human. Genetic association studies are being widely and appropriately used to identify potential genetic prognostic

FIGURE 1: Flow chart of study identification and specific reasons for exclusion from the meta-analysis.

factors and molecular biomarkers for genetically determined human diseases [30]. Due to their impact on the biological function of corresponding genes, candidate gene association studies have given priority to the well-characterized SNPs such as rs1801133 in exon 4 of the MTHFR gene. Kim et al. conducted a comparison of ONFH and control subjects using logistic regression models, revealing no significant association between SNP rs1801133 and ONFH susceptibility in a Korean population [28]. Chang et al., however, showed evidence that supported the involvement of this SNP in development of ONFH [26]. The disparate results across the

studies may at least partly be attributable to the relatively small sample sizes. This led us to perform a meta-analysis to determine the association in a larger sample size. When pooling all published data together, we found little evidence of a significant association between SNP rs1801133 and ONFH susceptibility, consistent with our hypothesis. A review of overall progress and contribution of candidate gene association studies to current understanding of the genetic susceptibility to cancer suggested that MTHFR C677T increased risk of gastric cancer (OR, 1.52; 95% CI, 1.31–1.77) [31]. Variation of SNP rs1801133 is associated with

decreased enzymatic activity and elevated homocysteine levels. Increased frequency of this SNP has been detected among patients with cardiovascular disease and coronary atherosclerotic disease [12, 32]. These data are suggestive of a possible effect on human diseases attributed to SNP rs1801133. On the other hand, we cannot exclude the possibility that these diseases are etiologically different and it is likely that SNP rs1801133 may not represent a contributing factor for ONFH. However, this aspect is worth to be proven with a very large-sized study.

Further analysis stratified by ethnicity also showed no association in Asians and in Caucasians. It has previously been reported that CT and TT genotypes have 65% and 30% of the MTHFR activity, respectively, suggesting individuals with these genotypes are at higher risk of various diseases, such as ONFH [33]. A frequency ranging from 5% to 40% in European populations [32] implicated that SNP rs1801133 may contribute to ONFH, especially among Caucasians. But the expected association was not detected in our study, which may still be caused by the limited sample size.

Results of a previous meta-analysis showed an association between MTHFR SNP rs1801133 and ONFH in non-Asian populations [34]. In this analysis, a total of eight studies (five on Caucasians) with 778 cases and 1,162 controls were included, possibly leading to a less reliable and comprehensive conclusion because of the smaller sample. We expanded our analysis by adding additional four studies, with no significant association identified. The uncertainty highlights the necessity to conduct subsequent studies to validate the presently unclear genetic association.

There are some limitations to this study. The ONFH individuals in our study were caused by different etiologies, including primary ONFH without special history, glucocorticoid intake, and alcohol abuse, which may affect the final results. There were significant heterogeneity among the studies, including ethnicity, number of individuals, and methodology. The total sample size may not generate sufficient power to detect the overall and ethnicity-specific effects in subgroups, and minor or moderate association may be masked. Additionally, the nonstandardized selection

of control population, such as healthy versus ONFH-free subjects, may introduce nondifferential misclassification bias. Lastly, estimation of age in ONFH susceptibility was not conducted due to lack of original data.

In conclusion, the current meta-analysis revealed that MTHFR SNP rs1801133 was not significantly associated with the development of ONFH. We found similar results in ethnicity-specific analysis. Considering ONFH can be caused by many factors such as application of glucocorticoid and alcoholism, these findings need further validation through future larger studies stratified by different etiological factors.

Conflict of Interests

The authors have declared that no conflict of interests exists.

Authors' Contribution

Wei Chai, Ming Ni, and Jiying Chen conceived and designed the research. Wei Chai, Peiliang Geng, and Guoqiang Zhang performed the research. Analysis and interpretation of data were done by Lewis L. Shi, Wei Chai, Ming Ni, Guoqiang Zhang, Zijian Lian, and Zhendong Zhang. Drafting and revising then writing the paper were done by Wei Chai, Zhendong Zhang, and Lewis L. Shi. Wei Chai and Zhendong Zhang contributed equally to this work.

Acknowledgments

The authors wish to thank all the clinical doctors who helped them in the Chinese PLA General Hospital. National Natural Science Foundation of China supports this research. The number is 81301564.
