Protein disulfide isomerases (PDI) are eukaryotic oxidoreductases that catalyze the formation and rearrangement of disulfide bonds during folding of substrate proteins. Structurally, PDI enzymes share as a common feature the presence of at least one active thioredoxin-like domain. Some organisms, such as yeast and mammals, have a family of PDI homologues that exhibit distinct domain organization and function [6–8].

1. Introduction

In eukaryotic cells, folding and posttranslational modifications of proteins are the primary function of the endoplasmic reticulum (ER) [1]. Formation of disulfide bonds, a common modification observed in several secretory proteins, takes place mainly in that compartment [1, 2]. Almost all organisms have a set of proteins involved in folding; however, the cellular and molecular details of this process have been elucidated only in a few model systems, such as the yeast ER and the bacterial periplasmic compartment [3, 4].

Protein disulfide isomerases (PDI) are eukaryotic oxidoreductases that catalyze the formation and rearrangement of disulfide bonds during folding of substrate proteins [5]. Structurally, PDI enzymes share as a common feature the presence of at least one active thioredoxin-like domain. Some organisms, such as yeast and mammals, have a family of PDI homologues that exhibit distinct domain organization and function [6–8].

Under physiological conditions, the cellular mechanisms that respond to proteotoxic stress remain in an inactive state; however, under stressful conditions, several response mechanisms are triggered to restore proteome stability, but if these fail, the apoptotic pathways are activated, leading ultimately to cell death [9, 10]. In addition to assisting oxidative folding of nascent polypeptides, PDI enzymes are also involved in holding, refolding, and degradation of unfolded or misfolded proteins under stressful conditions [10]. Furthermore, since the blocking of PDI activity could lead to protein misfolding, prolonged proteotoxic stress and apoptosis [11, 12] considering PDI as a therapeutic target to stop the progression of some diseases seem plausible [13, 14].

Human amebiasis, the parasitic infection caused by the protozoan Entamoeba histolytica, is a prevalent infection in developing countries [15]. Interestingly, the continued secretion of proteins, including virulence factors, is well recognized as the primary feature of this parasite [16]. Moreover, protein folding and correct disulfide bond formation...

\(^1\)New England Biolabs; \(^2\)Coli Genetic Stock Center; \(^3\)American Type Culture Collection.

are essential for secreted virulence factors, such as the Gal/GalNAc-inhibitable lectin [17] and the pore-forming peptide A (amoebapore A) [18].

The *E. histolytica* genome has 11 genes encoding PDI homologues [19]. From these, the enzyme named \(EhPDI\) \(38\) kDa polypeptide with two active thioredoxin-like domains has been used as a model to study protein folding and disulfide bond formation in *E. histolytica*. By using *in vitro* assays and standard substrates (such as insulin, lysozyme, and ribonuclease A), we have confirmed that \(EhPDI\) exhibits the distinctive oxidoreductase activities (reductase, oxidase, and isomerase) as well as the typical chaperone-like function (suppression of polypeptide aggregation) [20, 21]. Only the oxidase activity has been demonstrated *in vivo*, through functional complementation of the \(dsbA\) mutation in *E. coli* [22].

Here, to test whether \(EhPDI\) exhibits isomerase activity *in vivo*, we performed a functional complementation assay using the \(ΔdsbC\) mutant of *E. coli* as a model and the defective expression of the periplasmic protein AppA as the phenotype. The acid phosphatase-phytase enzyme (AppA) has three consecutive disulfide bonds and one nonconsecutive that renders it dependent on DsbC [23]. Our preliminary results showed that \(EhPDI\) exhibits isomerase activity; however, further mutagenic analysis revealed significant differences in the functional role of each thioredoxin-like domain. Finally, additional studies confirmed that \(EhPDI\) protects two heat-labile enzymes, \(α\)-glucosidase and NdeI endonuclease, against thermal inactivation, extending our knowledge about its chaperone-like activity.

2. Materials and Methods

2.1. Materials. DNA amplification reagents and DNA purification kits were from Qiagen (Valencia, CA). Bacterial media were from Becton Dickinson (Franklin Lakes, NJ). Electrophoresis reagents were from Bio-Rad (Hercules, CA). Endonucleases and other enzymes were from New England Biolabs (Ipswich, MA). Other biochemicals were from Sigma-Aldrich (St. Louis, MO), otherwise mentioned in the text. All reagents used were analytical or molecular biology grade.

2.2. Bacterial Strains, Plasmids, and Growth Conditions. *Escherichia coli* strains and plasmids used in this study are listed in Table 1. Bacterial cultures were grown in LB medium.
at 37°C, with appropriate antibiotics (ampicillin at 150 μg/mL and chloramphenicol at 15 μg/mL). Recombinant plasmids were constructed by using standard molecular cloning protocols.

2.2.1. Construction of pBAD-AppA Plasmid. Full-length sequence of the bacterial appA gene was amplified from genomic DNA (XL1-Blue MRβ strain), using the synthetic oligonucleotides EcAppAF (5′-cgc gag ttc atg ATT AAA AGC GGA AAC ATA TCG-3′) and EcAppAR (5′-cgc ggc tct aga TTA CAA ACT GCA CGG CGG TAT-3′) as primers. The PCR product was then digested with EcoRI and XbaI endonucleases and cloned into the EcoRI-XbaI sites of pBluescript SK-, yielding the pBlAppA plasmid. To obtain the pBAD-AppA plasmid, a site for EcoRV (located immediately upstream of the EcoRI) was used to get a restriction fragment from EcoRV-XbaI sites, which was then subcloned into Smal-XbaI sites of pBAD33. The appA gene was confirmed by DNA sequencing.

2.2.2. Construction of the pQRM05, pQRM06, and pQRM15 Plasmids. The EhPDI gene variants (with Cys to Ser substitutions) were amplified from its corresponding pBluescript-based plasmid (Table 1), using the synthetic oligonucleotides EhPDis38F (5′-cat cgc gaa ttc GCT GAT GTA TCA TTA AAT C-3′) and M13FW (5′-GTA AAA CGA CGG CCA GTG-3′) as primers. Then, PCR products were digested with BamHI and HindIII endonucleases and subcloned into the same sites of pQE30 (in frame with the sequence encoding the N-terminal hexahistidine tag). The EhPDI gene variants were confirmed by DNA sequencing.

2.3. DsbC Complementation and AppA Activity Assay

2.3.1. Periplasmic Expression of AppA and Coexpression with EhPDI. E. coli strains BW25113 (wild type) and JW2861-1 (ΔdsbC mutant) were transformed with pBAD33 (as control) or pBAD-AppA. Stable transformants were cultured in LB medium, supplemented with chloramphenicol, and the periplasmic expression of AppA was induced with 0.2% arabinose. Bacterial cell pellets (from 1 mL) were obtained by centrifugation (2 min at 10,000 rpm).

E. coli strain JW2861-1 harboring pBAD-AppA was transformed with pBluescript-based plasmids expressing EhPDI variants (Table 1). The plasmid pBluescript SK- was used as a control. Stable cotransformants were cultured in LB medium, supplemented with ampicillin and chloramphenicol, and the periplasmic coexpression of AppA and EhPDI was induced with 0.2% arabinose and 1 mM IPTG. Bacterial cell pellets were obtained as before.

2.3.2. Acid Phosphatase Activity Assay. The acid phosphatase activity was determined by a colorimetric assay [23]. Bacterial cell pellets were resuspended in glycine buffer (0.25 M; pH 2.5) and adjusted to 0.3–0.6 units of A400 per mL. Then, 20 μL aliquots were further diluted with 80 μL of the same buffer and mixed with 100 μL of 50 mM p-nitrophenyl phosphate. After 15 min of incubation at 37°C, reactions were stopped by adding 1 mL of 1.2 N NaOH. Immediately, supernatants were separated by centrifugation (5 min at 14,500 rpm) and the released p-nitrophenolate was quantified by measuring the A405. Light scattering by cellular debris was also considered (recording the A400). The acid phosphatase activity was expressed in Miller units [23, 24].

2.4. Purification of Recombinant EhPDI Enzymes. E. coli strain Shuffle Express was transformed with pQE30-based plasmids expressing recombinant EhPDI enzyme variants (see Table 1). Stable transformants were cultured in LB medium, supplemented with ampicillin, and protein expression was induced with 0.1 mM IPTG. Bacterial cells (from 100 mL) were harvested and lysed under native conditions, using the CellLytic B Plus Kit (Sigma-Aldrich). From the soluble fraction, recombinant proteins were purified by Ni-affinity chromatography (The QIAexpressionist, Qiagen). Eluate fractions were analyzed by SDS-PAGE and those containing more than 95% of pure protein were pooled and concentrated/desalted by ultrafiltration, using a Microsep UF Spin Filter (Pall Co.). Protein concentration was determined by performing the BCA colorimetric assay (Sigma-Aldrich), using BSA as a standard.

2.5. Oxidative Refolding Assay. Oxidative refolding of denatured-reduced ribonuclease A (drRNase) by recombinant amebic PDI enzymes was assayed by following a reported protocol [25]. Refolding was achieved by diluting drRNase (7.8 μM) into a reaction buffer (2 mM GSH, 0.4 mM GSSG, 100 mm Tris-HCl, pH 8.0) containing 5 μM of amebic PDI enzymes and 4.5 mM of cCMP (RNase substrate). The reactivation of RNase was followed for 60 min by recording the absorbance at 296 nm. Active RNase (μM) was calculated from the first derivative of the absorbance over time and corrected for the depletion of the substrate and the formation of the product (CMP, RNase inhibitor) [25]. The isomerase activity was determined from the linear increase of active RNase over time (μM/min), after the lag phase (which reflects the oxidase activity, min⁻¹).

2.6. Disulfide Reductase Assay. Disulfide reduction of bovine insulin catalyzed by recombinant amebic PDI enzymes was assayed according to a standard turbidity method [21, 26]. Recombinant enzymes (2 μM final) were added to a reaction buffer (2 mM EDTA and 100 mM HEPES; pH 7.0) containing bovine insulin (100 μM final). Disulfide reduction was started by adding DTT (0.3 mM final) and followed for 90 min by recording the A650 every 5 min. Reductase activity was determined from the linear increase of absorbance over time after the lag phase (A650/min⁻²) [27].

2.7. Chaperone Activity Assays. Chaperone-like activity of EhPDI was evaluated by performing a protection against...
thermal inactivation assay of two heat-labile enzymes: α-glucosidase [28, 29] and NdeI endonuclease [30, 31].

2.7.1. Thermal Inactivation of α-Glucosidase. Different concentrations of EhPDI (0–5 μM final) were added to a reaction buffer (50 mM KH₂PO₄; pH 6.8) containing yeast α-glucosidase (16 μg/mL final). Thermal inactivation was performed by incubating at 43°C for 60 min (a control without treatment was carried out for each concentration). Then, reactions were cooled on ice for 1 min and the aggregated protein was separated by centrifugation (5 min at 14,500 rpm). α-glucosidase activity was determined by diluting a 40 μL aliquot of the supernatant with 160 μL of reaction buffer containing 0.125 mM of reduced glutathione and 1.25 mM of p-nitrophenyl-α-D-glucopyranoside. After 20 min of incubation at room temperature, reactions were stopped by adding 50 μL of 0.5 M Na₂CO₃. The released p-nitrophenolate was quantified by measuring the absorbance at 415 nm. The α-glucosidase activity (AG) was defined by the increase in absorbance over time (ΔA₁₅/min). For each concentration of EhPDI, the percentage of protection against thermal inactivation (chaperone-like activity) was determined by using the following equation: protection (%) = (ΔA₅₇/ΔA₅₇) × 100, where ΔA₅₇ represents the remaining α-glucosidase activity after thermal treatment (60 min at 43°C), while the untreated enzyme is represented by ΔA₅₇.

2.7.2. Thermal Inactivation of NdeI Endonuclease. Different concentrations of EhPDI (0–2 μM final) were added to a reaction buffer (75 mM potassium acetate, 30 mM Tris-acetate, 15 mM magnesium acetate, 1.5 mM DTT; pH 7.9) containing NdeI endonuclease (1 U/μL final). Thermal inactivation was performed by incubating at 50°C for 30 min (control reactions without incubation were carried out). Then, the reactions were cooled on ice for 2 min and briefly centrifuged (to collect a 10 μL volume). Endonucleolytic activity was determined by adding 5 μL of a plasmid solution, containing 0.1 μg of pUC19 and 0.1 mg of BSA. After 2 hours of incubation at 37°C, standard agarose gel electrophoresis and ethidium bromide staining were used to analyze the restriction fragments. The NdeI endonuclease activity was defined by the relative amount of linearized plasmid, estimated by digital densitometry. For each concentration of EhPDI, the percentage of protection against thermal inactivation (chaperone-like activity) was determined by using the following equation: protection (%) = [(E₅₉ - C₂)/(C₁ - C₂)] × 100, where E₅₉ represents the remaining NdeI endonuclease activity after thermal treatment (30 min at 50°C), while C₁ (with NdeI) and C₂ (without NdeI) correspond to the control reactions without treatment.

2.8. Statistical Analysis. Unless otherwise mentioned, activity data were from three independent experiments and are represented as mean ± standard error. All statistical analysis were performed using Prism v.5 (GraphPad Software, San Diego, CA). Unpaired t-test was used for routine comparison of data sets. P values less than 0.05 were considered statistically significant.

3. Results and Discussion

3.1. EhPDI Exhibits In Vivo Isomerase Activity. To study the functional activities of eukaryotic PDI enzymes in vivo, yeast and bacterial cells have been successfully used to complement phenotypes associated with defective formation of disulfide bonds [32, 33]. In E. coli cells, the oxidative folding of polypeptides is carried out in the periplasmic compartment and performed by the Dsb proteins: oxidation and isomerization of disulfide bonds are catalyzed by DsbA and DsbC, respectively [34].

The DsbC protein is particularly notable since it shares structural and functional similarities with eukaryotic PDI enzymes [35]. In fact, its functional role as disulfide isomerase has been studied using eukaryotic multidisulfide proteins as substrates [35, 36]. Four physiological substrates of DsbC have been identified so far: AppA [23], RcsF [37], MepA, and RNase I [38]; from these, in vivo studies using AppA as substrate protein showed that DsbC plays an important role during folding of proteins with nonconsecutive disulfide bonds [23]. Then, to test whether EhPDI exhibits disulfide isomerase activity in vivo, we performed a functional complementation assay using the ΔdsbC mutant of E. coli as a model and the defective periplasmic expression of AppA as the phenotype.

Initially, the absence of acid phosphatase activity (as background) was confirmed, indicating that the chromosomal appA gene was not induced under our experimental conditions (data not shown). Then, pBAD-AppA (Table I) was used to transform both wild type and ΔdsbC mutant strains. Stable transformants were cultured and AppA expression was induced properly. As noted in Figure 1, a high level of acid phosphatase activity was detected in the wild type strain, 9595 ± 593 Miller units, whereas a low level of activity was observed in the ΔdsbC mutant (1593 ± 70 Miller units), confirming the DsbC-dependence of AppA (Figure 1).

![Figure 1: Acid phosphatase activity when AppA was expressed in the wild type and ΔdsbC mutant strains, as well as when it was coexpressed with EhPDI in the ΔdsbC mutant strain. The activity (expressed in Miller units) is shown on the left. The plasmids used for transfection of E. coli are also indicated.](image-url)
Table 2: In vivo isomerase activity of EhPDI enzyme variants.

The data was expressed as ± standard error (n = 6).

Under the background of ΔdsbC/pBAD-AppA, normalization was performed considering the mean activity of pBPelB-EhPDI as maximal (A_max = 5151) and pBluescript SK- as minimal (A_min = 780). The percentage (%) was calculated as [(A - A_min)/(A_max - A_min)] \times 100, where A represents the activity of the enzyme variant.

The activity ratio (%) was calculated as (variant/wild type) \times 100.

Then, pBPelB-EhPDI (Table 1) was used to transform the ΔdsbC/pBAD-AppA strain, using a two-plasmid system [39]. Stable cotransformants were cultured and protein expression was induced accordingly. Periplasmic expression of EhPDI was confirmed by immunoblot (data not shown). Interestingly, a significant increase in acid phosphatase activity was detected (5151 ± 344 Miller units), suggesting that the correct disulfide bond formation of AppA was assisted by the isomerase activity of EhPDI.

3.2. Isomerase Activity of EhPDI Is Limited and Dependent on Its Reductase Activity. The active site of the thioredoxin-like domains from DsbA, DsbC, and PDI enzymes is characterized by the presence of the motif CXXC, where the cysteine residues play an important role in the enzymatic activity [40, 41]. EhPDI contains two thioredoxin-like domains (referred to as N- and C-Trx, resp.; both having the motif CGHC) that are essential for its in vivo oxidative activity [20]. To test whether both domains contribute to the isomerase activity, we carried out mutagenic analysis followed by a functional complementation assay.

The pBluescript-based plasmids expressing EhPDI variants (Table 1) were used to transform the ΔdsbC/pBAD-AppA strain. Stable cotransformants were cultured and protein expression was induced accordingly. Periplasmic expression of EhPDI variants was confirmed by immunoblot (data not shown). As indicated in Table 2, the isomerase activity of EhPDI is dependent on its CGHC active sites, since a complete loss of the AppA activity was observed when the variant having both domains inactivated was coexpressed (EhPDISSSS). Also, low AppA activity was detected when each domain was tested without the background of the other (EhPDISSCC and EhPDICCSS); furthermore, the slight difference observed between these two variants can be explained by considering that the thioredoxin-like domains are not equivalent with regard to the isomerase activity [33, 42]. However, it is important to take into account the cellular features of the bacterial model to better understand the role of EhPDI as an isomerase in vivo.

In the periplasmic compartment, substrate proteins with misoxidized disulfide bonds are shuffled to properly oxidized states by two mechanisms: (1) the isomerase pathway, where DsbC acts on the substrate as reductase-oxidase, and (2) the reductase pathway, where DsbC simply acts as reductase, allowing DsbA another chance to correctly oxidize the substrate [43]. In addition, when the ΔdsbC mutant of E. coli was complemented with the protein TrxP from Bacteroides fragilis (a periplasmic reductase with poor isomerase activity), a fully restored AppA activity was observed, indicating that the disulfide bond isomerization of this substrate is accomplished mainly through the reductase pathway [43]. Hence, it is reasonable to think that the low AppA activity detected when the ΔdsbC mutant of E. coli was complemented with any of the variants (Table 2) suggests that the isomerase function of EhPDI is dependent on its reductase activity. To test this, we performed two in vitro activity assays, oxidative refolding of ribonuclease and reduction of insulin, using purified recombinant enzymes, that is, EhPDI variants.

As indicated in Table 3, the wild type (EhPDI) and variants (EhPDISSCC and EhPDICCSS) showed comparable oxidative refolding capabilities. In contrast, significant differences were observed in their reductive activities: EhPDISSCSS retained about 60%, whilst EhPDICCSS roughly retained 20%. These results confirmed that EhPDI is dependent on its reductase activity to function as oxidoreductase in vivo and in vitro.

3.3. EhPDI Protects Proteins against Thermal-Induced Aggregation. The chaperone-like function of PDI enzymes is determined by their ability to protect misfolded/unfolded substrate proteins against thermal-induced aggregation and to assist refolding [44, 45]. This function is essential in order for PDI to act as an efficient folding catalyst, since it allows access to buried thiols and disulfide bonds in the substrates and prevents nonspecific interactions between partially folded intermediates [1]. Typically, the chaperone-like function has been studied in vitro by measuring the ability to prevent protein aggregation induced by different physical or chemical conditions, such as temperature or denaturants [5, 46].

We have already reported that EhPDI exhibits chaperone-like function by showing its ability to prevent the DTT-induced aggregation of the B chain of insulin [21]. Although this assay was a simple approach to test the chaperone-like function of EhPDI, the low molecular mass of the substrate (3.4 kDa) represents a limitation of this assay, since it offers a restricted number of contact sites to form stable complexes [47]. Hence, to gain further insights regarding the
chaperone-like function of EhPDI, we performed additional in vitro assays to test its ability to prevent thermal-induced aggregation, using as substrates two heat-labile enzymes: \(\alpha\)-glucosidase and \(Nde\)I endonuclease.

As shown in Figures 2 and 3, the chaperone-like function of EhPDI was dose-dependent, since an increment of activity was observed as a result of augmenting its concentration. Moreover, to estimate its chaperone-like ability, the half-maximal effective concentration (EC\(_{50}\)) and Hill slope were calculated by fitting the data to a model of one specific binding site with a variable slope. Interestingly, the apparent values obtained for \(\alpha\)-glucosidase (EC\(_{50}\) = 3.0 ± 0.4 \(\mu\)M; Hill slope = 1.0) and \(Nde\)I endonuclease (EC\(_{50}\) = 0.26 ± 0.06 \(\mu\)M; Hill slope = 2.4) suggest that EhPDI exhibits differences in substrate specificity and affinity [48].

Although EhPDI does not have a substrate-binding b'-domain (a-a'-D) as the mammalian homologue (a-b-b'-a'-c) [49], the notion that some other domains (e.g., a' or D) might be involved in the chaperone activity is evident. This idea is supported by the results of two previous reports: (i) ERp46, which lacks a b'-domain, is able to bind peptides through its catalytic domains (a', a, and a') [50] and (ii) the D-domain of ERp29 contains a discrete and conserved substrate-binding site [51].

### 3.4. Closing Remarks

Although little is known about the \(E.\ histolytica\) mechanisms that act in response to proteotoxic stress [52], the upregulation of genes encoding typical chaperones (such as Hsp70 and Hsp90) in a response to thermal stress suggests that it contains the cellular machinery necessary to preserve and restore the stability of the proteome [53]. So, the identification and characterization of EhPDI as a folding catalyst with chaperone-like activity represents an additional step to dissect the molecular mechanisms involved in both protein folding and proteotoxic stress in \(E.\ histolytica\). Hence, it is conceivable to suppose that inhibition of EhPDI could lead to an increase in protein misfolding, promoting a sustained proteotoxic stress, eventually inducing apoptosis and, thus, preventing infection by this parasite.

### Conflict of Interests

The authors declare that there is no conflict of interests regarding the publication of this paper.
