Objective. Previously, we demonstrated that remote ischemic postconditioning (RipostC) improved postresuscitation myocardial and cerebral functions in rat. Here, we investigated the effects of RipostC alone and combined with therapeutic hypothermia (TH) on cardiac and neurological outcomes after CPR in swine. **Methods.** Twenty-one pigs were subjected to 10 mins of VF and then 5 mins of CPR. The animals were randomized to receive RipostC alone, or its combination with TH, or sham control. RipostC was induced by 4 cycles of limb ischemia followed by reperfusion. TH was implemented by surface cooling to reach a temperature of 32–34°C. **Results.** During 72 hrs after resuscitation, lower level of cardiac troponin I and greater stroke volume and global ejection fraction were observed in animals that received RipostC when compared to the control. RipostC also decreased serum levels of neuron-specific enolase and S100B and increased neurologic alertness score after resuscitation. The combination of RipostC and TH resulted in greater improvement in cardiac and neurological outcomes than RipostC alone. **Conclusion.** RipostC was conducive to improving postresuscitation myocardial and cerebral functions and reducing their organ injuries. Its combination with TH further enhanced its protective effects.

1. Introduction

Cardiac arrest (CA) is always a leading cause of death worldwide. It is estimated that 325,000 victims suffer out-of-hospital CA in the United States, accompanied with 350,000 in Europe and 544,000 in China every year [1–3]. Despite advances in cardiopulmonary resuscitation (CPR) methods and post-CA care, the improvement remains poor in survival rate and survival to hospital discharge with good neurological outcome in CA victims [4, 5].

The high rates of mortality and morbidity are mainly attributed to the severity of post-CA disease, which is typically characterized by brain damage, myocardial dysfunction, systemic inflammatory response, and coagulation disorder [6]. It is reported that 45%–60% of resuscitated patients exhibit severe and lethal myocardial dysfunction, which has been implicated as a major cause of early death after successful resuscitation [7, 8]. Moreover, postresuscitation

brain injury contributes to 68% of the death in CA victims, and nearly 60% survivors have moderate to severe cognitive deficits three months after resuscitation [9, 10].

Earlier, remote ischemic postconditioning (RipostC) emerged as an endogenous form of organ protection and has shown its potent protection of heart and brain against regional ischemia reperfusion (IR) injury [11–14]. Recently, we applied RipostC in a rat model of CA and resuscitation and demonstrated that RipostC significantly attenuated postresuscitation myocardial and cerebral dysfunctions and improved the duration of survival [15]. Further investigations are necessary to confirm the effectiveness of RipostC in larger-animal studies and clinical trials of CPR.

Currently, therapeutic hypothermia (TH) has been introduced into the clinic as the most effective treatment to reduce neurological impairment following successful CPR [16]. Additionally, some investigations have confirmed that mild hypothermia not only alleviated postresuscitation

neurological dysfunction, but also improved cardiac outcomes after resuscitation [17–19]. However, the improvement in postresuscitation neurological outcome and survival produced by TH is limited. Clinically following successful resuscitation, only 35.7% of out-of-hospital CA and 41% of in-of-hospital CA achieved a good neurological outcome at hospital discharge [20, 21]. New strategies should be explored to produce a greater effect of organ protection after resuscitation, which may be achieved by combining TH and other treatments.

In the present study, we translated the previous small-animal experiment into a clinically relevant, large-animal model. We investigated the effects of RIpstC on the outcomes of heart and brain after CPR in swine. In addition, the potential synergistic effect produced by combined RIpstC and TH was examined. We hypothesized that RIpstC would alleviate postresuscitation myocardial and cerebral dysfunctions and their organ injuries, which would be enhanced by its combination with TH.

2. Materials and Methods

2.1. Study Design. This was a prospective, randomized, controlled experimental study. A porcine model of cardiac arrest and resuscitation was utilized. The protocol of this study was approved by the Animal Care and Use Committee of the Medical School of Ningbo University. Animal care and experiments were conducted according to Institutional Animal Care and Use Committee guidelines.

2.2. Animal Preparation. Twenty-one male domestic pigs weighing 37 ± 2 kg were fasted overnight except for free access to water. Anesthesia was initiated by intramuscular injection of ketamine (20 mg/kg) and completed by an ear vein injection of sodium pentobarbital (30 mg/kg). An additional dose of sodium pentobarbital (8 mg/kg) was injected at hourly intervals to maintain anesthesia. A cuffed endotracheal tube was advanced into the trachea. The animals were mechanically ventilated with a volume controlled ventilator (SynoVent E5, Mindray, Shenzhen, China) with a tidal volume of 15 ml/kg, peak flow of 40 l/min, and FiO_2 of 0.21. End-tidal carbon dioxide (ETCO_2) was continuously monitored with a handheld $\text{ETCO}_2/\text{SpO}_2$ monitor (PMSH-300, SunLife Science Inc., Shanghai, China). Respiratory frequency was adjusted to maintain ETCO_2 between 35 and 40 mm Hg. The conventional lead II electrocardiogram was continuously monitored by applying three adhesive electrodes to the shaved skin of the right upper and left upper-and-lower limbs.

For the measurement of myocardial function such as stroke volume (SV) and global ejection fraction (GEF), a PiCCO Monitor (PiCCOplus, Pulsion Medical Systems, Munich, Germany) based on transpulmonary thermodilution was applied. A 7 F central venous catheter was inserted into the right internal jugular vein for the injection of iced saline. Another 4 F thermistor-tipped arterial catheter was inserted into the left femoral artery. The arterial and central venous catheters were connected to the PiCCO system for discontinuous monitoring of SV and GEF. For the measurement of aortic pressure and the collection of

blood samples, a fluid-filled 8 F catheter (Model 6523, C. R. Bard Inc., Salt Lake, UT) was advanced from the right femoral artery into the thoracic aorta. For the measurements of right atrial pressure and core (blood) temperature, a 7 F Pentalumen, thermodilution tipped catheter (Abbott Critical Care # 41216, Chicago, IL) was advanced from the right femoral vein into the right atrium. All catheters were flushed intermittently with saline containing 5 IU bovine heparin per ml. For inducing ventricular fibrillation (VF), a 5 F pacing catheter (EP Technologies Inc., Mountain View, CA) was advanced from the right external jugular vein into the right ventricle. The position of all catheters was confirmed by characteristic pressure morphology and with fluoroscopy. Blood temperature was maintained at $37.5 \pm 0.5^\circ\text{C}$ during baseline with the aid of a cooling/warm blanket.

2.3. Experimental Procedure

2.3.1. Animal Randomization. Fifteen minutes prior to inducing VF, baseline measurements were obtained. The animals were randomized with the Sealed Envelope Method into one of the three groups: (1) RIpstC, (2) RIpstC+TH, or (3) sham control.

2.3.2. Induction of VF and CPR. VF was induced by 1 mA alternating current through the 5 F pacing catheter, delivered to right ventricular endocardium. Mechanical ventilation was discontinued after onset of VF. Prior to initiating the resuscitation protocol, the pacing catheter was withdrawn to avoid heart injury during chest compression. After 10 mins of untreated VF, CPR was manually performed by a ratio of 30 : 2 of compression to ventilation. The position of chest compression was located in the midline at the level of the fifth interspace. The compression quality was continuously monitored by an E Series Monitor Defibrillator (ZOLL Medical Corporation, Chelmsford, MA) to guarantee a compression depth of ≥ 50 mm at a rate of ≥ 100 per minute. The ventilation was performed by a CPR simple respirator with room air. After 2.5 mins of CPR, the first bolus of epinephrine at a dose of $20 \mu\text{g/kg}$ was administered. After 5 mins of CPR, defibrillation was attempted with a single 150-J biphasic waveform electrical shock delivered between the conventional right infraclavicular electrode and the apical electrode with the E Series Monitor Defibrillator. If an organized rhythm with a MAP of greater than 50 mm Hg persisted for an interval of 5 mins or more, the animal was regarded as successfully resuscitated. With failure to achieve return of spontaneous circulation (ROSC), chest compression and ventilation were immediately resumed for 2 mins prior to another defibrillation. The protocol was repeated until successful resuscitation or for a total of 15 mins. Additional doses of epinephrine were administered at an interval of 3 mins after the first bolus injection. If recurrent VF occurred after resuscitation, a 150-J electrical shock was attempted.

2.3.3. Application of RIpstC and TH. RIpstC was induced at the beginning of CPR. Four cycles of remote ischemia were performed in animals that received RIpstC. Each cycle of remote ischemia was performed by 5 mins of bilateral

upper limb ischemia followed by reperfusion for 5 mins. Limb ischemia was induced by inflating a 5 cm wide blood pressure cuff around the upper third of the limb to stop the arterial blood supply. During the ischemic period, the cuff was inflated to 200 mm Hg for 5 mins, followed by deflation for 5 min reperfusion. At 5 mins after resuscitation, TH was implemented by surface cooling with the aid of a cooling blanket and ice packs to reach a temperature of 32–34°C until 4 hrs after resuscitation, followed by a rewarming rate of 1°C/h for 4 hrs.

2.3.4. Postresuscitation Care. Following ROSC, mechanical ventilation was continued with FiO_2 of 0.21 for 4 hrs. Thereafter, all catheters were removed and wounds were surgically sutured. The endotracheal tube was removed when the animal recovered from anesthesia and had spontaneous respiration. The animals were then returned to their cages and observed for an additional 68 hrs. The surviving animals had free access to water and food but no other treatments. At the end of 72 hrs after resuscitation, the animals were euthanized with an intravenous injection of 150 mg/kg sodium pentobarbital. A necropsy was routinely performed for documentation of possible injuries to the bony thorax and thoracic and abdominal viscera resulting from the surgical or CPR intervention or the presence of obfuscating diseases.

2.4. Measurement. Electrocardiogram, aortic and right atrial pressures, blood temperature, and pulse oxygen saturation were continuously recorded by a patient monitoring system (BeneView T6, Mindray, Shenzhen, China). Coronary perfusion pressure (CPP) was calculated as the difference between decompression diastolic aortic and time-coincident right atrial pressure measured at the end of each minute of precordial compression. The value of ETCO_2 was continuously recorded by the handheld $\text{ETCO}_2/\text{SPO}_2$ monitor.

SV and GEF, as the indexes of myocardial function, were measured at baseline and hourly after resuscitation for a total of 4 hrs with the PiCCO system. Serum concentration of cardiac troponin I (cTNI), which indicated the severity of cardiac injury, was measured at baseline and at 2 hrs, 4 hrs, and 24 hrs after resuscitation with enzyme-linked immunosorbent assay (ELISA) kits (Meixuan Biotechnology Inc., Shanghai, China) according to the manufacturer's instructions. Aortic blood pH, PCO_2 , PO_2 , hemoglobin, and lactate concentrations were measured at baseline and at 2 hrs and 4 hrs after resuscitation on 1.5 ml of arterial blood samples with a Blood Gas/Electrolyte Analyzer (Model 5700, Instrumentation Laboratory, Lexington, MA).

Neurological function was evaluated according to the method of neurologic alertness score (NAS) developed by Tang et al. [22] at 24 hr intervals for a total of 72 hrs. This quantitative NAS was based on the modifications of quantitative neurological deficit score [23]. The alertness score is acquired according to objective grading of level of consciousness, respiration, posture, water intake, eating, and self-care. The NAS was scored from 0 (coma) to 100 (fully alert). In earlier studies, the alertness score was highly correlated with the neurological deficit score ($r = -0.97$) [24]. The NAS was examined and confirmed by two investigators

who were blinded to the study. Serum concentrations of neuron-specific enolase (NSE) and S100B, considered as biochemical markers of cerebral injury, were measured at baseline and at 24 hrs, 48 hrs, and 72 hrs after resuscitation with ELISA kits (Meixuan Biotechnology Inc., Shanghai, China).

2.5. Statistical Analysis. Continuous variables were presented as mean $\pm$ SD when data were normally distributed or as a median (25th, 75th percentiles) when data were not normally distributed. Normal distribution was confirmed with the Kolmogorov-Smirnov test. Variables were compared with one-way analysis of variance (ANOVA) or the Kruskal-Wallis test for nonparametric data. Comparisons between time-based measurements within each group were performed with repeated-measurement analysis of variance. If there was a significant difference in the overall comparison of groups, comparisons between any other two groups were made by the Bonferroni test. For the comparison of categorical variables such as ROSC, Fisher's exact test was used. A value of $P < 0.05$ was considered significant.

3. Results

There were no significant differences in baseline hemodynamics, body temperature, arterial lactate, myocardial function, and serum biomarkers of heart and brain among the three groups (Tables 1, 4, and 5).

During CPR, the same trend of CPP was observed in all animals, in which the values were not significant among the three groups (Table 2). Six of the seven animals in each group were successfully resuscitated. No differences were observed in duration of CPR, epinephrine dosage, and number of shocks that were required for establishing ROSC and subsequent incidence of recurrent VF among the three groups (Table 3).

During 1.5 hrs after resuscitation, body temperature was rapidly decreased from $37.1 \pm 0.5^\circ\text{C}$ to $34.5 \pm 0.5^\circ\text{C}$ in the combination group. Thereafter, a temperature of 32–34°C was maintained until 4 hrs after resuscitation in animals that received hypothermia, followed by a rewarming rate of 1°C/h for 4 hrs (Figure 1).

Following the observation of 4 hrs after resuscitation, both of SV and GEF were significantly decreased in all animals when compared to the baseline values, which indicated significantly impaired myocardial function. However, postresuscitation myocardial function was gradually improved in all animals. The values of SV and GEF were significantly higher in the R1postC alone and combination groups than those in the control group. Additionally, the values of SV and GEF were both greater in the combination group than the R1postC alone group, in which the differences were significant among the two groups at 4 hrs after resuscitation (Figures 2 and 3). cTNI kept increasing after resuscitation in all animals. However, slower increases in cTNI were observed in the R1postC alone and combination groups, in which the values were significantly lower than the control group at 4 and 24 hrs after resuscitation. 24 hr cTNI was significantly lower in the combination group than the R1postC group (Table 4).

The same levels of arterial lactate were observed at baseline and after resuscitation in the RipostC alone and combination groups, which returned to baseline levels in both groups at 4 hrs after resuscitation, and were significantly lower when compared with the control group (Table 4).

The same duration of survival of 72 hrs was achieved in all resuscitated animals. An even rate of survival was observed at 72 hrs after resuscitation among the three groups. However, significantly higher NAS were observed in the RipostC group than the control group. The combined RipostC and TH

further improved postresuscitation neurological function, in which NAS was significantly higher than that in the RIpostC and control groups (Table 5). The levels of NSE and S100B were lower in animals that received RIpostC alone and combined with TH, which were statistically significant at 48

and 72 hrs after resuscitation when compared to the control group. 72 hr NSE and S100B were significantly lower in the combination group than the RIpostC group (Table 5).

At necropsy, no significant abnormalities were observed on gross examination in all animals.

4. Discussion

In the present study, we employed a clinically relevant, large-animal model and demonstrated that remote ischemic conditioning via bilateral upper limbs was successfully induced at the stage of reperfusion during CA and resuscitation. Milder postresuscitation myocardial and neurological dysfunctions and reduced organ injuries of the heart and brain were achieved in animals that received RIpstC. In addition, the combined RIpstC and TH produced a greater effect of organ protection than the RIpstC alone and further improved postresuscitation cardiac and neurological outcomes.

During post-CA care, the degree of damage of heart and brain is closely related to the survival and quality of life of CA victims. New therapeutic strategies are needed to optimally mitigate the damage of these vital organs and therefore improve the prognosis of patients. RIpstC, serviced as ideal noninvasive and easily performed means, can be a feasible option. Previously, our group investigated the potential effectiveness of RIpstC in CA and resuscitation. A rat model was employed, and two limbs were chosen to implement RIpstC. Remote ischemic conditioning was finished by four cycles of 5 mins of limb ischemia and then 5 mins of reperfusion. RIpstC initiated during CPR or after successful resuscitation both significantly alleviated postresuscitation myocardial and cerebral dysfunctions [15]. In the present study, the same algorithm of remote stimulus was chosen to implement coincident with the beginning of CPR in swine. Improved myocardial and cerebral functions after resuscitation were also observed in animals that received RIpstC. Additionally, RIpstC mitigated postresuscitation cardiac and cerebral damage, as indicated by lower levels of serum biomarkers. These favourable outcomes might be attributed to two points: (1) During 5 mins of CPR, the ischemic period of RIpstC was induced by inflating the cuff around the bilateral upper limbs to stop their blood supply. Thus, a greater blood flow might be assigned to nearby vital organs such as the brain. (2) Considering that the severity of postresuscitation cardiac and cerebral dysfunction would get worse as the time went on, an earlier intervention such as RIpstC might prevent or slow down the process of cardiac and cerebral damage. Recently, a similar study demonstrated that RIpstC significantly reduced serum concentrations of biomarkers for cardiac damage but only slightly improved ventricular function and neurological recovery after resuscitation [25]. It might be due to a relatively shorter arrest of 8 mins and delayed RIpstC started 10 mins after resuscitation; the latter might weaken or lose the efficacy of organ protection. In a rat study of regional IR injury, the time window of intervention has occurred in the protective effects of RIpstC, in which cardiac protection was evident when applied 10 mins after reperfusion but disappeared when applied 30 mins after reperfusion [26].

Although cardiac and cerebral protection produced by RIpstC was manifested in our CA models, its potential mechanisms are unclear. Earlier investigations have confirmed that oxidant injury, inflammation, and cell apoptosis are all involved in the pathologic mechanisms of cardiac and cerebral injuries after successful CPR [27–30]. However,

whether the protective effects of RIpstC are related to the alleviation of the above-mentioned pathological damage has not been explored. However, in diverse animal models of regional IR injury, RIpstC has been proven to provide cardiac and cerebral protection via the inhibition of oxidant injury, inflammation, and apoptosis. Li et al. [11] demonstrated that RIpstC significantly decreased myocardial infarction through the reduction in oxidant injury. Yu et al. [12] demonstrated that RIpstC protected the heart by modulating cell apoptosis through increasing the levels of Bcl-2/Bax and decreasing the levels of caspase-3. Another two studies demonstrated that RIpstC significantly attenuated brain injury; the neuroprotective mechanisms were potentially mediated by the reduction of oxidative stress and inflammatory response and also the anti-apoptotic action [13, 14].

In an attempt to enlarge the protective effects of vital organs after resuscitation, the effectiveness of combined RIpstC and TH was investigated. We chose a shorter duration of hypothermia of 4 hrs based on our previous study [31]. Mild hypothermia was induced by surface cooling to aim at a temperature of 32–34°C. Targeted temperature was quickly reached within 1.5 hrs and then maintained until 4 hrs after resuscitation. Synergistic protective effects were observed in the combination group, which resulted in greater improvements in postresuscitation myocardial and cerebral functions with lower levels of injury biomarkers when compared to the RIpstC alone. Considering that the protective efficacy of TH may be partly dependent on the duration of hypothermia, a longer duration of mild hypothermia may confer a stronger protective effect to the combination group [32].

Currently, no investigation has explored the interactive mechanisms of RIpstC and hypothermia. However, animal studies have confirmed that TH protected postresuscitation heart and brain by decreasing oxidant stress, inflammation, and apoptosis. Earlier, Ostadal et al. [33] demonstrated that HT produced cardiac protection through the suppression of oxidative stress following CA. Recently, another two studies demonstrated that TH protected post-CPR heart and brain by reducing the expression of inflammatory cytokines and cell apoptosis [28, 29]. This similar pathological damage may be further alleviated by the combination of TH and RIpstC so as to produce greater protection of heart and brain after resuscitation. Future investigations are required to clarify the protective mechanisms of RIpstC and its interaction with TH in CA models.

There were some limitations in this study. First, we did not set the TH alone group. It is unknown whether better cardiac and neurological outcomes after CPR would be achieved by the combined RIpstC and TH than the TH alone. However, recent investigations demonstrated that under the condition of hypothermia remote ischemic conditioning still produced potent protection of vital organs [34, 35]. Thus, RIpstC and TH might simultaneously reduce postresuscitation pathological damage so as to produce greater protection of heart and brain than the TH alone. Second, although we have observed postresuscitation cardiac and cerebral protection induced by RIpstC during this shorter observation period, we could not see the overall process of body recovery after CPR. A

longer observation period would be better to fully evaluate the effectiveness of RlpostC in the future animal studies and clinical trials.

5. Conclusion

RlpostC was conducive to improving postresuscitation myocardial and cerebral functions and reducing their organ injuries in a porcine model of CPR. Its combination with TH further enhanced its protective effects.
