Biology of inflammation in Crohn’s disease: Mechanisms of action of anti-TNF-α therapy

Stephan R Targan MD

Over the past three years, progress toward understanding the pathogenesis of Crohn’s disease (CD) has accelerated as a result of scientific achievement on two fronts. First, over 30 different animal models of mucosal inflammation, created by genetic or cellular manipulations, have focused attention on the inflammatory mediators that are central to the development of ileitis and colitis. Second, the availability of inhibitors of specific inflammatory molecules, particularly antitumour necrosis factor-alpha (TNF-α), has allowed the role of such molecules in human disease to be ascertained.

The central abnormality in human CD and most animal models is an imbalance of proinflammatory and anti-inflammatory mediators in the mucosa. An enhanced T helper (Th) (Th1, interferon-gamma [IFN-γ] and/or TNF-α) response, and/or lack of a counterregulatory T-regulatory (Tr) (Tr1, interleukin [IL]-10) or Th (Th3, trans...
normal immune response.

antigen presence, may result in a lack of downregulation of inflammation. Inflammatory bowel disease (IBD) pathogenesis may be the result of an abnormal immune response to a common antigen or may represent a failure to suppress the normal immune response.

Normal mucosa is in a state of perpetually controlled or orchestrated inflammation, characterized by an intricate balance of immune mediators in response to various antigenic stimuli in a genetically regulated environment (1). Failure of normal regulatory mechanisms, and perhaps persistent antigen presence, may result in a lack of downregulation of inflammation. Inflammatory bowel disease (IBD) pathogenesis may be the result of an abnormal immune response to a common antigen or may represent a failure to suppress the normal immune response.

Macrophages and Th1 cells help to promote inflammation by producing proinflammatory cytokines, including IL-1, IL-6, IL-8, IL-12, TNF- and IFN-, all of which incite inflammation (2,3). Production of Th1-type cytokines is stimulated by TNF- (4,5). Macrophages and Th2 cells produce anti-inflammatory cytokines, which include IL-4, IL-10, TGF- and IL-1 receptor antagonist.

THE ‘IMMUNOSTAT’

The therapeutic effect of cytokines in the regulation of inflammation may be to reset the immune response, the immunostat, so that secretion of Th1 cytokines is balanced against that of Th2, Tr1 or Th3 cytokines. The immunostat properties of cytokines may persist beyond the point where the therapeutic cytokine can be measured (in the case of cytokine therapy) or where its absence can be detected (as with the use of anticytokines). The extended clinical effect of anti-TNF- therapy, long after any antibody can be detected in the patient, may be explained by the fact that the level of IFN- production in the intestine (as opposed to the periphery) is dependent upon the presence of TNF- and suggests a mechanism by which anti-TNF- may reset the mucosal immunostat.

THE ROLE OF TNF-α IN THE PATHOGENESIS OF MUCOSAL INFLAMMATION AND IBD

Several studies have detected increased TNF- protein and mRNA levels in mucosal biopsies from patients with CD (6,7); others have not (8,9). Several recent trials of intravenously administered anti-TNF- monoclonal antibody therapy have shown dramatic responses in CD (10,11). These results show a primary role for TNF- in the mediation of altered mucosal immune function and inflammation in CD. The extended duration of clinical responses (up to one year) in a small proportion of patients treated with a single infusion of anti-TNF- may be due to one or more mechanisms, including the elimination of soluble TNF-, blockade of transmembrane TNF- function or the elimination of a cell or cells expressing transmembrane TNF-. Thus, the removal of TNF- for a relatively short period of time by anti-TNF- antibodies results in a prolonged and sustained downregulation of the hyperactive inflammatory state. Anti-TNF- therapy in the treatment of human CD retains its effect long after elimination of the antibodies. This finding suggests that the most important effect of blocking TNF- is a protracted adjustment of the level of immune response within the mucosa.

The mechanism by which TNF- regulates inflammation in the gut of patients with CD is likely complex and multifactorial. To determine this mechanism, a series of in vitro experiments were performed using specimens from patients participating in clinical trials of anti-TNF- (12,13). The role of TNF- in induction of the hyperactive T-cell state known to be present in CD mucosa was evaluated in 10 patients with steroid-resistant disease (13). In this small study, nine of 10 patients were evaluated at baseline and four weeks after administration of a single infusion of anti-TNF-monomclonal antibody. Nine attained clinical and endoscopic remission, and six of the nine patients maintained remission for eight weeks. The leukocyte chemoattractant RANTES, derived from activated T cells, was detectable in biopsy specimens taken at baseline, but not in samples taken four weeks after the infusion (12). These results demonstrate that anti-TNF- downregulates the number, or activation state, of mucosal T cells and suggest that TNF- is critical for the maintenance of the hyperactive T-cell state in CD.

The lengthy duration of response to one infusion of anti-TNF- monoclonal antibody was examined in another series of in vitro studies, performed in conjunction with an open-label trial. In patients responsive to treatment with anti-TNF-, there was sequential downregulation of TNF- and IFN- production in the mucosa. Th1 T cells were not eliminated; rather, their function was reduced in inflamed mucosa to a level comparable with that seen in noninflamed mucosa. This reduction in Th1 cytokines suggests
that TNF-a-augmented Th1 function, not simply Th1 function, was critical for disease pathogenesis. This decrease in Th1 cell function persisted throughout the duration of the clinical response (13).

Both studies demonstrated that anti-TNF- therapy has a profound effect on the level and function of activated T cells within the mucosa, and confirmed that both a hyperactive T-cell state and enhancement of Th1 cytokine are central to pathogenesis. The presence of soluble or transmembrane TNF-in the mucosa plays a critical role in the maintenance of this heightened and shifted T-cell response. Finally, the data suggest that the prolonged clinical benefit seen with anti-TNF- therapy may be affected through partial reversal of these altered processes.

Monocytes, macrophages and T cells are the major producers of TNF- (14). Increased TNF- levels are associated with sequential increases in IL-1, IL-6 and IL-8 (15), and vice versa. This correlative response suggests that TNF-functions early in the inflammatory cascade and that enhancement of Th1 cytokines is central.

TNF-appears to have an important role in regulation of the inflammation that characterizes CD (13,16-21). Patients with IBD have greater numbers of mucosal TNF-producing cells (21-23) and higher levels of mucosal TNF-(17-21) than healthy individuals.

**EXPERIMENTAL MODELS OF CYTOKINE REGULATION OF MUCOSAL INFLAMMATION**

Several rodent models of mucosal inflammation have been refined using cellular and molecular manipulations of mucosal T-cell regulation. Most of these animals develop colitis marked by overproduction of Th1-type cytokines, particularly IFN- and TNF- More recently, a rodent model of mucosal inflammation characterized by increased numbers and activity of Th2 cytokine production (IL-4) has been generated by deletion of the T-cell receptor-alpha gene in mice (23).

In Th1-type models, inhibition of the specific cytokines responsible for initiation of a T-cell response (eg, anti-IFN-, anti-TNF- or anti-IL-12) either eliminates or ameliorates the development of mucosal inflammation. Treatment of these animals with the Th1 downregulatory cytokine, IL-10 (Tr1), with or without stimulation of local TGF- (Th3) production, also inhibited inflammatory responses (24). The roles of any one cytokine, a combination of cytokines and anticytokines, developed to counteract their effects in human disease, can only be determined by clinical trials in populations of patients with IBD.

Several studies in rodent models have defined TNF- as a critical factor in mucosal inflammation. The first model to indicate such a role for TNF- was the CD4+ CD45RBhigh T-cell transfer to congenic or semisyngeneic mice with severe combined immunodeficiency disease. The resulting inflammation was more severe in the large intestine, and pathogenesis was characterized by the overproduction of Th1-type cytokines (IFN-) (25,26). This model system is similar to at least two-thirds of CD patients in whom cytokine secretion undergoes a shift to a Th1 phenotype (25,26). Production and synthesis of Th1 cytokines appear to be important for disease pathogenesis in this model, because treatment with recombinant IL-10, anti-IFN- or anti-TNF-monoclonal antibodies (inhibitors of Th1 development and function) attenuates or completely eliminates the colitis (24).

Using a mouse model of trinitrobenzene sulphonic acid (TNBS)-induced colitis, several studies have highlighted the importance of TNF- in mucosal inflammation. In this model, the successful elimination of disease with administration of anti-IFN-, anti-TNF- or anti-IL-12 monoclonal antibodies has proved that the colitis is Th1-dependent (25-27). In another investigation, mice with chronic colitis were treated by intraperitoneal injection of antibodies to TNF- and showed a marked improvement of both clinical and histopathological signs of disease (25-27).

The predominant role of TNF- in colitis was further demonstrated by the finding that much more severe, indeed lethal, disease could be induced in TNF-transgenic mice with TNBS-induced colitis (27). No significant colitis could be induced in mice in whom the TNF-gene had been inactivated by homogeneous recombination. Complementation of TNF-function in TNF/mice by expression of a mouse TNF-transgene was sufficient to reverse this effect (25). These studies, therefore, have provided direct evidence of a predominant role of TNF-in mouse models of Th1-mediated chronic intestinal inflammation. Other studies using the TNBS model have demonstrated a dominant pathogenic role of Th1 T-cell-derived cytokines, suggesting that TNF-may regulate inflammation by modulation of IFN-production (25-27). Determination of the mechanism by which TNF-regulates Th1 cytokines may lend great insight into a component of the critical regulatory processes that initiate and perpetuate chronic intestinal inflammation.
