Nonalcoholic fatty liver disease: A clinical approach and review

Maitreyi Raman MD, Johane Allard MD

Nonalcoholic fatty liver disease (NAFLD) is the most common cause of incidental elevation of liver enzymes in North America and Europe. Risk factors for NAFLD include body mass index of 25 kg/m² or greater, central obesity and diabetes mellitus. The spectrum of disease is variable, ranging from simple steatosis with benign prognosis, to nonalcoholic steatohepatitis and cirrhosis, conferring increased morbidity and mortality. The primary abnormality or ‘first hit’ in patients with NAFLD is insulin resistance leading to hepatic steatosis. The second hit involves multiple proinflammatory cytokines resulting in nonalcoholic steatohepatitis. Treatment is aimed at aggressive risk factor control and weight loss. Currently, there are no pharmacological agents recommended in the treatment of NAFLD, although preliminary studies suggest promising agents in the future.

Key Words: Insulin resistance; Nonalcoholic fatty liver disease; Obesity

Epidemiology and Risk Factors

The conventional risk factors for the development of primary NAFLD include type II diabetes, insulin resistance, hyperlipidemia and obesity (2). NAFLD typically affects 50% of diabetics and 76% of obese patients (3,4), and is the most common of all liver diseases. However, the prevalence of NAFLD is substantial lesser, affecting 18.5% of obese patients. Other traditional risk factors include hyperuricemia, central obesity defined as waist circumference greater than 100 cm in males and greater than 88 cm in females, and hypertension. Secondary causes of NAFLD include nutrition-related complications, such as total parenteral nutrition, rapid weight loss, and intestinal jejunoileal bypass surgery (Table 1). Certain drugs are associated with NAFLD (Table 2). Metabolic syndromes and pregnancy-related fatty liver diseases are also some of the secondary causes of NAFLD. Patients with normal body mass index (BMI) may develop NAFLD even in the absence of traditional risk factors. It is thought that the primary abnormality may be occult insulin resistance or central adiposity (5). The natural history of NAFLD still remains poorly defined.

Mortality among NAFLD patients approaches 13%, which is greater than age- and sex-matched controls (6). Because these patients often have features of the metabolic syndrome, they are at high risk for cardiac-related death. Hence, both ischemic heart disease and malignancy are the leading causes of death in patients with NAFLD. However, liver disease is the third most common cause of mortality in this population, accounting for 13% of all deaths. This is significantly different than patients without NAFLD, in whom liver-related causes of mortality account for less than 1% of all deaths (6). Clinical predictors of more advanced disease include people with diabetes, hypertriglyceridemia (7) and those older than 40 years of age.

Diagnosis

Most patients with NAFLD are asymptomatic or suffer from nonspecific symptoms and signs such as fatigue, malaise or right upper quadrant pain. In most cases, the diagnosis is suspected in
features of grade 2 plus the additional requirement of portal cyttes, and some lobular inflammation. Grade 3 shows all the microvesicular with ballooning present in zone 3 hepatocytes and shows moderate steatosis, usually mixed macrovesicular and microvesicular with ballooning present in zone 3 hepatocytes, and some lobular inflammation. Grade 3 shows all the features of grade 2 plus the additional requirement of portal

Currently, the only method of distinguishing simple steatosis from NASH is the liver biopsy. Brunt et al (10) proposed a grading and staging system for NASH. Grade 1 reveals mild steatosis, predominantly macrovesicular with minimal ballooning of hepatocytes and minimal inflammation. Grade 2 shows moderate steatosis, usually mixed macrovesicular and microvesicular with ballooning present in zone 3 hepatocytes, and some lobular inflammation. Grade 3 shows all the features of grade 2 plus the additional requirement of portal fibrosis and stage 4 reveals cirrhosis with or without perisinusoidal fibrosis.

The first hit results in fat accumulation within the liver parenchyma. This occurs in abnormalities during uptake, synthesis and secretion of lipids resulting primarily from insulin resistance, which is quite common in patients with NAFLD (11). Insulin resistance is often a primary abnormality in patients with NAFLD. There is often a genetic predisposition to insulin resistance, even in the absence of frank diabetes. Twenty per cent of the nondiabetic population may exhibit insulin resistance. Patients that exhibit more pronounced levels of insulin resistance exhibit a greater degree of steatosis (12). Central adiposity may contribute to the flow of excess free fatty acids (FFAs) to the liver by providing a direct route through the portal vein (13). Patients with NAFLD often have risk factors such as type II diabetes, hyperlipidemia, hypertension and obesity, which are part of the insulin resistance syndrome. Hyperinsulinemia promotes lipolysis in the adipocyte, resulting in increased FFAs delivered to the liver. In the hepatocyte, FFAs stimulate synthesis of more FFAs and inhibit oxidation of FFAs (14). Insulin sensitivity is also influenced by peptide mediators, otherwise known as adipocytokines, such as tumour necrosis factor-alpha (TNF-α), leptin and adiponectin and although the mechanisms by which this occurs remain largely unknown, theories are suggested. TNF-α influences steatosis by stimulating the release of FFAs from adipocytes into the liver. TNF-α may directly induce apoptosis of hepatocytes promoting activation of hepatic stellate cells, stimulating fibrosis (15). Leptin potentially may stimulate platelet-derived
growth factor, ultimately leading to hepatic stellate cell proliferation resulting in fibrosis (16). Adiponectin may have a protective role against fatty liver. Recently it was shown that adiponectin levels were significantly reduced in patients with NAFLD compared with controls resulting in an inverse relationship between insulin resistance and adiponectin levels (17). This observation may result in a future therapeutic role in the pharmacological management of NAFLD.

**Second hit**

The second hit is hepatocellular injury that results from oxidative stress, lipid peroxidation and direct cellular toxicity from FFAs (18). Multiple mechanisms regarding hepatocyte injury have been proposed:

1. Increased expression of cytochrome P450 isoform CYP2E1 has been shown to occur in patients with NASH. CYP2E1 is a pro-oxidant, resulting in increased production of reactive oxygen species, capable of peroxidizing cell membranes.

2. Increased insulin leads to peripheral lipolysis resulting in excess fatty acids which catalyzes lipid peroxisomes. Peroxisomes are involved in the oxidation process of fatty acids. Oxidation, along with binding and export of fatty acids, is the primary method of protecting the liver from subsequent damage.

3. The peroxisome proliferators activated receptor-alpha (PPAR-\(\alpha\)) is responsible for regulating the esterification and export of fatty acids in very low density lipoprotein, in the binding of fatty acids and in mitochondrial and peroxisomal oxidation. Reduced expression of PPAR-\(\alpha\) may have an important role in the pathogenesis of NASH (19).

4. Mitochondrial abnormalities have been described in patients with NASH, but not in those with simple steatosis. These mitochondrial abnormalities lead to increased mitochondrial fatty acids beta-oxidation, eventually resulting in free radical formation hepatocyte injury and steatohepatitis. Patients who are insulin resistant but do not have mitochondrial abnormalities may develop fatty liver; however, generally they do not progress to steatohepatitis (20).

**MANAGEMENT**

**Conservative management**

Currently, management is aimed at lifestyle modification, primarily targeting weight loss achieved through dietary modification and exercise. Additionally, treatment of all other aspects of the metabolic syndrome must be instituted. Weight loss and exercise both improve insulin resistance (21), which theoretically should improve steatosis. No randomized controlled study has been run to evaluate whether histological improvement occurs in patients with steatohepatitis or fibrosis after weight loss, although case reports and open-label studies suggest improvement. Weight loss should not exceed more than 1 kg per week, because rapid weight loss can exacerbate steatosis. Similarly very low calorie diets that give less than 500 kcal/day and jejunoileal bypass surgery should be avoided as a method of weight loss, due to the risk of worsening fibrosis. The recommended target for weight loss is 10% of a person’s body weight over a six-month period (22).

Multiple popular diets exist as methods of weight loss. Some diets are founded on years of medical experience, while others have deviated substantially from mainstream medical advice. The Weight Watchers program is one of the traditional models, restricting portion sizes and total calories consumed. Other popular diets include carbohydrate restriction without fat restriction (Atkins diet), macronutrient and glycemic load modification (Zone diet) and fat restriction (Ornish diet). In obese patients with BMI greater than 35 kg/m\(^2\), no significant differences were found regarding amount of weight lost at the end of one year (23). Reduction of cardiovascular risk factors correlated with amount of weight loss. Weight loss of 3 kg to 6 kg over one year was achieved regardless of type of diet followed. Currently, no data exist regarding various types of diets in patients with NASH.

**Weight loss medications**

Weight loss-inducing medications are not routinely used in the treatment of NAFLD, and have not been studied in randomized clinical trials. One case series suggested that orlistat in patients with NASH was safe, and showed significant histological improvement in both degree of steatohepatitis and fibrosis after six to 12 months of therapy (24). Orlistat is a reversible inhibitor of gastric and pancreatic lipase, and is one of two agents that have been approved for the management of obesity. This medication forms a covalent bond with the active serine residue of gastric and pancreatic lipase in the stomach and small bowel, blocking the digestion and absorption of dietary triglycerides. Orlistat in combination with a controlled energy diet, rather than diet alone, significantly increased weight loss in obese adults after one year of therapy (25).

The second approved drug in the management of obesity is sibutramine. Sibutramine was evaluated in one nonrandomized study in patients with NASH (26). Sibutramine in combination with a low calorie diet-induced weight loss improved insulin resistance and transaminases, as shown by ultrasonographic regression in fatty liver, compared with diet alone. It is a noradrenaline-serotonin reuptake inhibitor and produces weight loss by a dual mechanism: reduction of food intake and increase in energy expenditure. Average weight loss is in the range of 5% to 8% from baseline. Recently, rimonabant, a selective cannabinoid-1 receptor blocker, has been shown to improve cardiovascular risk factor profile and reduce body weight (27). Over 1000 overweight patients with BMIs between 27 kg/m\(^2\) and 40 kg/m\(^2\) participated in this study examining the effects of rimonabant and metabolic risk factors. Mean weight loss was 6.6 kg over 12 months at a dose of 20 mg. Additionally, waist circumference was reduced, plasma high density lipoprotein levels increased, and plasma adiponectin levels were significantly higher in patients receiving rimonabant compared with placebo. This medication, and other weight-reducing agents, may represent future therapeutic options for the pharmacological treatment of obese patients with NASH.

Certainly, diet should be combined with exercise to initiate and maintain weight loss. Exercise will enhance calorie deficit necessary for weight loss. A minimum of 30 min of moderate sustained activity five days per week is necessary to gain health benefits from exercise (28). Any fitness regimen should include a balance of aerobic exercise, strength and flexibility training.
Pharmacotherapy evaluated in the treatment of NAFLD

Currently, there are no approved pharmacological options for the treatment of NAFLD. Only three randomized controlled trials have been conducted to evaluate the efficacy of medical treatment in NAFLD (Table 3). The agents studied include antioxidants with vitamins E and C in combination, ursodeoxycholic acid and metformin. Although there was improvement in liver enzymes and steatosis in the trial evaluating metformin, there was no improvement in steatohepatitis or fibrosis at follow-up. The other two trials did not suggest any improvement in liver enzymes, steatosis, steatohepatitis or fibrosis. The remaining trials performed to date have been observational in design, had small sample size, and have had a short follow-up period. The thiazolidinediones are a class of insulin-sensitizing agents used to treat type 2 diabetes. Troglitazone was evaluated in an open-label trial involving 10 patients for duration of four to six months (29). These patients had improvement in transaminases and liver histology. However, this medication was subsequently withdrawn from the market due to serious hepatic toxicity. Both rosiglitazone (30) and pioglitazone (31) have been studied in open-label design, and have shown improvement in transaminases, steatosis and fibrosis. Recently VSL#3 was shown to lower markers of lipid peroxidation in patients with NASH (32). However, larger randomized studies are needed before routine recommendation of these agents in the treatment of NASH.

Bariatric surgery

Historically, there have been reduced prevalence and severity of liver disease after bariatric surgery. However, in some of these studies, there has been progression of liver disease in patients postoperatively. In the early age of bariatric surgery, jejunoileal bypass was the procedure most commonly performed. A substantial proportion of patients developed advanced liver disease, presumably from bacterial overgrowth and endotoxemia in the bypassed intestine, resulting in bacterial translocation and liver disease. However, the jejunoileal bypass surgery has seldom been performed in recent years due to the multiple complications arising from this procedure. A recent meta-analysis suggested that surgical therapy for weight loss was superior to other methods of weight loss in patients with BMI greater than 40 kg/m² (33). This weight loss was sustained for a 10-year follow-up. Although there was a trend toward improved weight loss in patients with BMI between 35 kg/m² and 39 kg/m² in the surgically treated group, the data cannot be considered conclusive. Recently, one study evaluated laparoscopic surgical weight loss via one of three techniques: roux-en-Y gastric bypass, laparoscopic adjustable gastric band and sleeve gastrectomy in patients with established NAFLD and metabolic syndrome. Mean BMI was 56 kg/m² (34). Patients had liver biopsies at the time of the bariatric surgery followed by a repeat biopsy after 15 months. Mean excess weight loss at the time of the second biopsy was 59%. There was a marked improvement in liver steatosis, steatohepatitis and fibrosis. In fact, in some patients, inflammation and fibrosis completely resolved. Additionally, there was improvement in the metabolic risk factor profile. Hence, as newer methods of bariatric surgery become more popular, there may be a future role for this type of surgery in morbidly obese patients with NASH.

Role of liver biopsy

Often, NAFLD is a diagnosis of exclusion. Patients are given advice regarding lifestyle modifications and re-evaluated clinically and biochemically several months later in routine follow-up. This may be a reasonable approach for the time being because there are no effective medications in the treatment of NAFLD. However, as pharmacotherapy becomes an option in the future, this line of thought may need to be revised. The distinction between pure fatty change and steatohepatitis can only be made histologically. This distinction is important because NAFLD has a benign prognosis, whereas NASH progresses toward cirrhosis. Because of the risk of NASH in patients suspected to have fatty liver, it could be argued that all patients should be offered a liver biopsy to stage the disease. However, in terms of logistics, cost and side effects, this may not be possible. Hence, it is reasonable to biopsy patients with risk factors for more advanced disease such as advancing age, obesity, hypertension and diabetes mellitus. Additionally, the liver biopsy may occasionally reveal unsuspected abnormalities indicating an alternate or additional diagnosis to fatty liver.

CONCLUSIONS

As the obesity epidemic continues to grow, the incidence and prevalence of NAFLD will increase as well. The primary abnormality appears to be that of intrinsic insulin resistance. The natural history of NAFLD is quite variable, ranging from benign disease to decompensated disease resulting in ascites, variceal bleeding, hepatocellular carcinoma or death. Currently, no pharmacological therapies are approved for the treatment of NASH. The mainstay of treatment continues to be weight loss therapy through diet and exercise, and aggressive risk factor control. Although some drugs appear to be favourable in pilot studies in the treatment of NASH, further randomized controlled studies are needed before routine recommendations of these agents.
