CLINICAL VIGNETTE

Occupational head-butting and skin nodules

Jana Pilkey MD FRCPC1, Karen McClean MD FRCPC2

CASE PRESENTATION

A 28-year-old veterinary student presented with nodules on her forehead. Two weeks earlier, she had been butted in the head by a ram while working with a herd. She sustained a small abrasion over the left frontal area of her head. Six days after the injury, she noted the development of local erythema, swelling and pruritus. She had no fever, chills or systemic symptoms. Self treatment with topical polymyxin B sulfate/bacitracin zinc (Polysporin, Pfizer Inc, USA) yielded no improvement in the lesions.

At her initial assessment, two weeks after the injury, an examination showed three lesions above the left eyebrow, one measuring 1.5 cm × 0.6 cm and the other two measuring 0.3 cm to 0.5 cm in diameter. The lesions were vesicular, with an erythematous rim. Lymphadenopathy was not detected and there was no ocular involvement.

Within five days after her initial presentation, the lesions became nodular and the erythematous rim more vivid (Figure 1). Tender preauricular lymphadenopathy developed, and she reported fatigue and general malaise but remained afebrile. Aspiration of a lesion was done to obtain material for culture. Hematology and chemistry laboratory investigations were within normal limits.

Two days later, she developed fever and chills, with periorbital and facial edema. Blood cultures were negative. Intravascular involvement was ruled out with an examination by an ophthalmologist. Despite 72 h of intravenous clindamycin phosphate (600 mg every 8 h), the edema and lymphadenopathy worsened and she was switched to meropenem 1 g intravenously every 8 h. Improvement was detected within 48 h, and she completed a 10-day course.

As the edema resolved, the nodular lesions developed a superficial crust, which subsequently separated, revealing underlying papillomatous lesions. Over the next three weeks, the lesions slowly decreased in size and erythema. Complete healing without scarring ensued.

What was the cause of her skin lesions?

DISCUSSION
Orf, also known as contagious pustular dermatitis or contagious ecthyma, is an uncommon infection in humans (1,2). It is caused by a DNA parapox virus and spread by direct contact with sheep, goats or, rarely, by fomite transfer from infected animals (1-5). In sheep and goats, Orf presents as a pustular eruption of the mouth and mucous membranes (3-6).

The diagnosis of Orf in humans is usually clinical and, therefore, physicians must be aware of the natural progression of the lesions to avoid misdiagnosis or harmful intervention. The incubation period varies from three days to four weeks of the lesions to avoid misdiagnosis or harmful intervention. Therefore, physicians must be aware of the natural progression of the lesions to avoid misdiagnosis or harmful intervention. The incubation period varies from three days to four weeks

Orf lesions are typically painless. Systemic effects, including lymphangitis, lymphadenitis and fever, are uncommon (1,3,4,6). Lesions are most often solitary, and occur on the hands of people who have been in contact with sheep or goats (1-7). Facial involvement is considerably less common (1,4,8), and ocular involvement is very rare (9). Bacterial superinfection is also considered to be an uncommon complication. Only one case series reported isolation of typical bacterial pathogens from Orf lesions (10). These pathogens were isolated in only nine of 119 cases (10). There are no reports in the literature of Orf itself causing extensive local edematous reactions in humans.

Orf is typically diagnosed on clinical grounds in patients with compatible lesions and a history of sheep or goat exposure (1,4). When in doubt, confirmation of the diagnosis can be achieved by viral culture and electron microscopy of material aspirated from lesions. Under electron microscopy, the virions appear brick or ovoid shaped, measuring 200 nm to 300 nm × 150 nm to 250 nm (3). Serological tests are available but are primarily used in epidemiological studies (1,4).

Orf is not a reportable disease and, therefore, the true incidence in Canada is unknown. Orf should be considered in the differential diagnoses of focal skin lesions in individuals with direct or indirect contact with sheep or goats. Except for the infrequent complication of secondary infection, no specific interventions are necessary. Because Orf lesions resolve without scarring (over four to six weeks), biopsy should generally be avoided. In the present case, we confirmed the diagnosis by viral culture of a lesion aspirate and reassured the patient that, despite the dramatic appearance of the lesions, scarring was unlikely.
