Incidental finding and management of intralobar sequestration of the lung in a 24-year-old man

Dhanjit Litt MD1*, Sumeet Gandhi MD1*, Sacha Bhinder MD2, Maurice Blitz MD3, Kieran McIntyre MD2

Pulmonary sequestration is described as a dysplastic mass of lung tissue that lacks communication with the tracheobronchial tree and receives systemic rather than pulmonary arterial blood supply. Two distinct classifications, intralobar and extralobar, have been described. The present article discusses the etiology, clinical and radiographic features of pulmonary sequestration as well as the management of this condition when it is discovered incidentally.

Key Words: Congenital lung conditions; Extralobar sequestration; Intralobar sequestration; Lung bud anomalies

Learning Objectives
• Review the etiology, clinical and radiographic features of intralobar sequestration (ILS) of the lung.
• Discuss the management of ILS when it is discovered incidentally.

CanMEDS Competency: Medical expert; Manager

A 24-year-old man presented to the emergency department with a 48 h history of abdominal pain. A computed tomography (CT) scan of the abdomen was suggestive of acute appendicitis. Incidentally, cystic dilation of air spaces was noted in a region occupying the right lower lobe. Following appendectomy, the inpatient respirology service was consulted. His medical history was significant for childhood asthma treated with inhaled corticosteroids and short-acting beta agonists as needed. In the summer of 2011, he was diagnosed with community-acquired pneumonia with consolidation in the right lower lobe; CT was performed to rule out potential empyema. CT showed a 7.5 cm × 5.0 cm × 5.0 cm mass located in the right lower lobe. The patient was treated with a seven-day course of oral antibiotics as an outpatient; the diagnosis was radiographically confirmed. Further investigation revealed the presence of an aberrant artery arising from the subdiaphragmatic aorta. After successful division of the feeding vessel, the lesion was derived from the celiac artery (Figures 2A and 2B) and resection of the right lower lobe was performed. Intraoperative blood loss was minimal and there were no postoperative complications. The patient was discharged home on postoperative day 3.

The resected specimen revealed an affected area of fibrotic and hemorrhagic tissue located inferiorly in the right lower lobe. The lesion measured 7.5 cm × 5.0 cm × 5.0 cm and extended to the pleural surface, where a ragged appearance with fibrous adhesions was noted. Microscopically, a well-demarcated area of cystically dilated bronchoalveolar spaces lined by ciliated respiratory epithelium with a scant lymphocytic stromal infiltrate was observed (Figure 3). The surrounding parenchyma on both gross and histological examination was normal. Collectively, these findings supported the diagnosis of ILS.

CASE PRESENTATION

A 24-year-old man presented to the emergency department with a 48 h history of abdominal pain. A computed tomography (CT) scan of the abdomen was suggestive of acute appendicitis. Incidentally, cystic dilation of air spaces was noted in a region occupying the right lower lobe. Following appendectomy, the inpatient respirology service was consulted. His medical history was significant for childhood asthma treated with inhaled corticosteroids and short-acting beta agonists as needed. In the summer of 2011, he was diagnosed with community-acquired pneumonia with consolidation in the right lower lobe; CT was performed to rule out potential empyema. CT showed a 7.5 cm × 5.0 cm × 5.0 cm mass located in the right lower lobe. The patient was treated with a seven-day course of oral antibiotics as an outpatient; the diagnosis was radiographically confirmed. Further investigation revealed the presence of an aberrant artery arising from the subdiaphragmatic aorta. After successful division of the feeding vessel, the lesion was derived from the celiac artery (Figures 2A and 2B) and resection of the right lower lobe was performed. Intraoperative blood loss was minimal and there were no postoperative complications. The patient was discharged home on postoperative day 3.

The resected specimen revealed an affected area of fibrotic and hemorrhagic tissue located inferiorly in the right lower lobe. The lesion measured 7.5 cm × 5.0 cm × 5.0 cm and extended to the pleural surface, where a ragged appearance with fibrous adhesions was noted. Microscopically, a well-demarcated area of cystically dilated bronchoalveolar spaces lined by ciliated respiratory epithelium with a scant lymphocytic stromal infiltrate was observed (Figure 3). The surrounding parenchyma on both gross and histological examination was normal. Collectively, these findings supported the diagnosis of ILS.

DISCUSSION

Pulmonary sequestration was first described by Huber in 1777. It is characterized as a dysplastic mass of lung tissue that lacks communication with the tracheobronchial tree and receives systemic rather than pulmonary arterial blood supply (1). Pulmonary sequestration can be further classified into two distinct types: intralobar and extralobar. These differ based on clinical features, location, pleural covering and venous drainage (Table 1). Pulmonary sequestration is a rare condition and is encountered at a rate of less than one case per year at tertiary referral centres (2).

The etiology of ILS is unclear, with evidence equally supporting both acquired and congenital hypotheses. The latter is well described...
by Pryce (1), who proposed that ILS occurs as a result of either the formation of an accessory lung bud or due to the capture and subsequent traction of a tip of the developing lung by a systemic artery. An alternative explanation was later offered by Smith (3), who proposed that the initial defect was in the primitive pulmonary arterial supply. According to Smith (3), a lack of blood flow to the developing lung leads to the retention of vessels from the primitive dorsal aorta, and exposure to systemic arterial pressure after birth leads to the changes observed. Recently, the observation that ILS is more commonly encountered in adults and that coexisting congenital anomalies in this condition are rare has lead to the proposal that ILS is an acquired phenomenon. Although the details are yet to be established, it has been suggested that an unknown trigger serves as a stimulus for the development of an aberrant systemic arterial supply in late childhood or early adulthood (4).

The key to establishing the diagnosis of ILS lies in identifying the aberrant arterial supply. Both CT and magnetic resonance imaging have proven to be effective in this regard. However, multidetector CT angiography is emerging as the diagnostic test of choice because it is better able to simultaneously visualize and provide details of the arterial supply, lung parenchyma and venous drainage (5-7).

Classically, ILS in adults has been identified in the work-up for recurrent lower respiratory tract infections (2). Our patient was once previously treated for right lower lobe pneumonia and this was, in fact, very likely an infection of the sequestrum. However, the diagnosis of ILS in the present case was made incidentally, during imaging for a completely unrelated condition. We found that current guidelines did not offer recommendations for management in this case.

Traditionally, as a preventive measure or as a treatment option for recurrent pneumonia, most centres recommend early surgical resection (8). Potentially adding further support for early resection are recent case reports that describe more severe complications such as life-threatening hemorrhage and malignant transformation (9,10). However, it is important to note that in the largest case series on ILS published to date, a large percentage of patients were asymptomatic (2). Also, although it would be difficult to study, it is possible that the number of patients with undiagnosed ILS is greater than those who develop symptoms. Finally, although severe complications, such as malignant transformation, have been documented in case reports, we should remain cognizant of the fact that these are extremely rare occurrences.

Given that the patient was currently asymptomatic, with only one previously documented lower respiratory tract infection, we presented two management options to him: close follow-up with surgical resection should he become symptomatic versus immediate preventive resection. The patient opted for the latter.

**CONCLUSION**

ILS is a rare congenital lung anomaly that can present in adulthood. As advanced imaging modalities become more routine and available, the diagnosis of ILS as an incidental finding will likely become more
common. Although most centres recommend early resection, given that many patients remain asymptomatic and that severe complications are rare, close outpatient follow-up may be a reasonable management option for patients with ILS discovered incidentally. In the absence of established guidelines, the decision to proceed with resection should be made with the patient on a case-by-case basis when ILS is discovered incidentally.

**Post-test**

- What is the etiology of ILS of the lung?
  The exact etiology of ILS is uncertain. There is evidence supporting both acquired and congenital hypotheses.

- What is the imaging modality of choice to establish a diagnosis of ILS of the lung?
  Both magnetic resonance imaging and CT are effective in identifying that aberrant arterial supply and, thus, establishing the diagnosis of ILS. However, given its ability to better simultaneously visualize the arterial supply, pulmonary parenchyma and venous drainage, multidetector CT angiography is emerging as the diagnostic test of choice.

- How should one proceed when ILS of the lung is discovered incidentally?
  Current guidelines offer no recommendations regarding how to proceed with incidental ILS. Most centres perform early surgical resection on all cases of ILS. However, given that many patients remain asymptomatic and that severe complications are rare, close outpatient follow-up may be a reasonable management option when ILS is discovered incidentally.
