Salmonella spp. is the cause of commonly encountered infections, with seasonal pattern of occurrence and worldwide distribution. Some of the clinical manifestations such as gastroenteritis and bacteremia are common, whereas others like mycotic aneurysms and osteomyelitis are infrequent especially in immunocompetent patients. *Salmonella* has been rarely described as a cause of myocarditis in the literature. We describe a case of an 18-year-old previously healthy male patient with myocarditis after *Salmonella enteritidis* infection. Clinical manifestations and diagnostic approach of this severe complication are discussed with a review of the literature.

1. Introduction

Myocarditis, clinically defined as inflammation of the myocardium, has a broad spectrum of causes including infectious, immune-mediated, and toxic [1]. The role of viruses as etiological factors, especially coxsackievirus and adenovirus, has been thoroughly investigated over the years [1]. The role of bacterial infections is obscure, as these infections are thought to be less commonly associated with myocarditis [1]. Nontyphoidal *Salmonella* gastroenteritis is a food-borne infection, which is usually self-limited. Bacteremia or other invasive complications are rare in immunocompetent persons.

We present a previously healthy male patient with acute myocarditis following *Salmonella enteritidis* infection. We also discuss the role of biomarkers of cardiac injury, ECG, echocardiogram, and endomyocardial biopsy in the diagnosis of myocarditis, in cases that follow infection with *Salmonella* spp.

2. Case Report

A 18-year-old previously healthy male presented to the emergency department (ED) of our hospital, with a 48-hour

history of >20/day profuse, watery, nonbloody diarrheas, 5 times of vomiting, generalized abdominal pain and fever up to 40°C. His previous medical record was clear from coronary artery risk factors or any other pathology. On the same day and before attending our ED, he had visited another hospital. No laboratory studies were performed there, and after administration of i.v. liquid and electrolyte replacement, he was discharged with the diagnosis of gastroenteritis. Of relevance, 2 days before the onset of symptoms, the patient had eaten fried rice with egg and chicken in a Chinese restaurant.

Physical examination on admission to the hospital revealed temperature 40.1°C, blood pressure 110/80 mmHg, heart rate 100 per minute, and respiratory rate 25 per minute. Cardiac examination was normal. Abdominal examination demonstrated generalized tenderness.

Laboratory tests performed in our ED showed increased leucocytes (14400) with neutrophilia (NE: 12400, LY: 700, MO: 1300), hemoglobin 16.6 g/dL/hematocrit 48.7%, sodium 138 mmol/L, and potassium 4.21 mmol/L with normal urea and creatinine levels (26 mg/dL and 1.1 mg/dL, resp.) and elevated C-reactive protein (11.28 mg/dL with upper limit normal (ULN) 10). Creatine phosphokinase

FIGURE 1: Laboratory results of cardiac biomarkers during hospitalization in a patient with *Salmonella enteritidis* associated acute myocarditis.

(CK): 107 U/L (ULN: 171), aspartate aminotransferase (AST): 19 IU/L (ULN: 35), and lactate dehydrogenase (LDH): 155 IU/L (ULN: 247) were normal (Figure 1). The electrocardiogram (ECG) performed in the ED was also normal, exhibiting upslope displacement of ST segment in precordial leads due to early repolarization (changes without clinical significance in young adults) (Figure 2(a)).

Admittance to our department was decided on the basis of clinical markers of dehydration, related to increased number and volume of diarrheas, and considering that the patient had sought medical help twice during a short period of time, indicating possibly the severity of symptoms or other more obscure and severe underlying pathology. Replacement of i.v. fluids (0.9% NaCl) and electrolyte losses was initiated with subsequent improvement in the patient's clinical condition.

After 24 hours of hospitalization, the patient complained of chest discomfort for the duration of 30 minutes, with no pain reflection, no pain relief with any changes in body position, and absence of pleuritic pain characteristics. The ECG during that episode was without any changes from the one on admission. Troponin-I (TnI) (qualitative assay) was normal and symptoms resolved.

Few hours later, laboratory tests revealed slight elevation of CK (258 U/L), while AST and LDH levels were within normal limits (29 IU/L and 197 IU/L, resp.) (Figure 1). A new ECG did not reveal changes compared to the previous ones, while an echocardiogram (ECHO) was also performed. It was normal without hypokinetic areas. The left ventricular ejection fraction was 70%, and there was no pericardial fluid. TnI test was positive (qualitative assay) at that time, and assessment with a quantitative assay showed remarkable elevation of TnI (23 ng/mL; ULN: 0.4) (Figure 1).

Consequently, the patient was transferred to the coronary care unit for cardiac monitoring. AST, CK, and LDH reached maximum values on the third day of hospitalization (55 IU/L, 392 U/L, and 249 IU/L, resp.). AST and CK alongside with TnI became normal on the fourth date and LDH on the sixth day (Figure 1). The ECG evolved with T wave inversion in lead III and biphasic T wave in leads V₄ and V₅ on the third day (Figure 2(b)). Abnormal Q waves were not

observed at any timepoint. ECG normalized on the sixth day before his discharge from the hospital.

Myocardial infarction was ruled out based on the lack of coronary artery risk factors and the age of our patient, and the diagnosis of acute myocarditis was established. On the third day of admission and after diarrhea and fever had resolved, *Salmonella enteritidis* was isolated from the stool culture. Tests for other infectious causes of myocarditis were negative. Considering that clinical manifestations of heart involvement occurred simultaneously with those of gastroenteritis, and no other possible causes (drugs and autoimmune diseases) could be recognized, *Salmonella* was identified as the causative agent of acute myocarditis in this patient.

Our patient remained asymptomatic with no relapse of symptoms. Additionally to fluids and electrolytes, ramipril at low dose (2.5 mg per day) and acetylsalicylic acid (100 mg per day) were administrated and were continued following his discharge from the hospital. ECHO was repeatedly normal with identical features to those described above. ECG and biomarkers of cardiac injury (CK and TnI) became normal as reported above. He was discharged after six days of hospitalization with followup from the cardiology outpatient clinic of our hospital. Nine months later (up to the time this paper was written), he remained in an excellent condition and with no indications of evolution to dilated cardiomyopathy.

3. Discussion

Myocarditis presents with a broad spectrum of clinical manifestations ranging from mild chest pain to cardiogenic shock and death [1]. Apart from the primary risks of developing fulminant heart failure or arrhythmias, dilated cardiomyopathy and chronic heart failure is the most dreadful and devastating long-term complication of myocarditis [1]. In a large single center, prospective study myocarditis accounted for 9% of cases of dilated cardiomyopathy [16]. Bacterial myocarditis is considered less frequent than myocarditis following viral infections and usually involves immunocompromised hosts or cases of sepsis with concomitant myocardial dysfunction [1]. Myocarditis occurring almost at the onset of bacterial gastroenteritis has been rarely reported in the literature, with *Campylobacter spp.* and *Salmonella spp.* being the main responsible bacteria. The lack of clinical suspicion and the high percentage of self-limited clinical course contribute to the underestimation of the true incidence of myocarditis in general.

In our literature review, we have included cases of *Salmonella* myocarditis, and we discuss current trends on the use of diagnostic tools employed to establish the diagnosis in these instances (Table 1) [2–15].

In the case presented, our patient was immunocompetent, and no bacteremia or sepsis could be established as possible explanation of myocardial involvement. It is worth mentioning that the duration of symptoms was only 30 minutes with complete resolution of chest pain, while usual biomarkers of cardiac injury (CK, AST, and LDH) were only

TABLE 1: Diagnostic approach to myocarditis due to *Salmonella* spp. in published case reports.

Ref.	<i>Salmonella</i> spp.	Clinical presentation	Biomarkers of cardiac injury	Troponin detection	ECG	Echocardiogram	Biopsy

mildly elevated. ECG had initially no pathological findings, and ECHO performed was repeatedly normal. These observations show that myocardial involvement might have been possibly left unrecognized without determination of cardiac troponin I.

There are six previous reports on the use of cardiac troponin in the diagnosis of *Salmonella* myocarditis [10–15], while the diagnostic value of this biomarker is well established in the literature for myocarditis [17, 18]. Cardiac troponin has limited sensitivity (34%) for the diagnosis of myocarditis with a specificity reaching 89% [18]. Still, compared to other biomarkers of cardiac injury, its sensitivity prevails (CK and CK-MB) for the detection of myocyte injury in myocarditis. We have always to keep in mind that cardiac troponin has low negative predictive value, indicating that normal values do not exclude myocardial injury. As indicated by our case and previous reports [10–15], the use of troponin is recommended in patients with gastroenteritis who complain of chest pain, regardless of the duration of symptoms.

ECG clearly remains a useful tool for the diagnosis of myocarditis. Even though findings exclusive for myocarditis, do not exist, serial ECG findings are characteristic and often extremely helpful for the distinction from acute myocardial infarction [1]. Certain ECG abnormalities like the presence of Q waves or left bundlebranch block are reported to have prognostic value [19, 20]. In a study involving mostly cases with idiopathic myocarditis the presence of ECG abnormalities had low sensitivity (47%) [19]. In our review of cases with *Salmonella*-associated myocarditis, ECG changes were present in all but 2 of them in which ECG was not performed (Table 1) [4, 8]. Whether differences amongst myocarditis of diverse etiologies exist in terms of ECG findings needs further investigation.

Echocardiography is valuable in the diagnostic evaluation of myocarditis though no specific findings exist and all patterns of cardiomyopathy have been described in this clinical entity [1, 21]. ECHO can detect wall motion abnormalities, disturbances of ventricular function, whose presence has prognostic value, and can also distinguish

fulminant from acute myocarditis [22]. Of relevance, with the use of ECHO, other causes of cardiac dysfunction can be excluded, serial monitoring of patients performed, and response to treatment assessed. Repeated ECHO evaluations in our patient was normal, as was also the case in other 2 previous reports (Table 1) [9, 10].

The application of novel imaging techniques and especially of contrast-enhanced magnetic resonance imaging (MRI) is very promising in the diagnostic assessment of patients with myocarditis [23]. The use of MRI should be considered especially in circumstances where both conventional imaging methods and other diagnostic tools fail to detect myocardial dysfunction.

Endomyocardial biopsy (EMB) still remains the gold standard for establishing the diagnosis of myocarditis with the use of Dallas criteria [24]. However, low sensitivity (ranging from 10% to 22% in various reports), sampling errors, variability in interpretation of samples, and lack of prognostic value have raised concerns on the diagnostic limitations of EMB [1, 25]. Recently, recommendations regarding patients who will benefit from EMB and, therefore, should undergo this procedure have resolved the above mentioned issues [26]. New imaging techniques, especially MRI with performance of MRI-guided EMB, seem to be very promising considering the reduction of sampling errors during EMB and the increase in sensitivity [26]. Taking into account the self-limited course of myocarditis in our patient, we did not consider performing EMB. Review of the literature revealed no cases that had undergone EMB for *Salmonella* myocarditis. To our knowledge, positive EMB are reported only from necrotomies. These data reflect the above-mentioned difficulties, limitations of the procedure, and the increasing trend to perform EMB in selected group of patients.

4. Conclusions

Myocarditis after *Salmonella* spp. infection is rare though its real incidence remains unknown. As evolution to dilated cardiomyopathy and sudden death are known complications of myocarditis, its occurrence must be excluded in patients with gastroenteritis who complain of chest pain.

Our review of the current diagnostic approach of patients with possible myocarditis clearly shows the absence of a single marker or procedure to establish the diagnosis. Even though new assays and imaging techniques are extremely helpful and promising, it is the physician's diagnostic suspicion that will guide the diagnostic evaluation with the proper tools in order to rule out other causes of cardiac dysfunction and verify myocarditis.
