Human Papillomavirus Infection and Cervical Dysplasia

Sharon Bond

Human papillomavirus (HPV) infection is highly prevalent and a common cause of abnormal cytology, particularly among young, sexually active women. With hybrid capture system assay, HPV can be further classified into low-risk (6, 11, 42, 43, 44) and high-risk (16, 18, 31, 33, 35, 45, 51, 52, 56) DNA types. The majority of HPV infections are believed to regress spontaneously. However, the natural history of infection in a particular woman and factors associated with individual persistence and/or regression are unknown. Persistent infection, especially with a high-risk type, may place a woman at increased risk for progression to high-grade squamous intraepithelial lesions (HGSIL) and perhaps cervical cancer.

Shown here is a case of a 25-year-old woman with progressive cervical intraepithelial neoplasia (CIN) over 15 months. The initial Pap smear suggested a low-grade squamous intraepithelial lesion (LGSIL). A cervigram (A, 10 o’clock to 11:30 o’clock) was obtained and colposcopically directed biopsies confirmed CIN I. An HPV DNA test was positive for high-risk HPV types. Repeat evaluation 1 year later yielded cytologic, biopsy, and cervicographic evidence of HGSIL compatible with CIN III (B). She was treated with large loop excision of the transformation zone.
