Chlamydia trachomatis (CT) is the most common cause of bacterial sexually transmitted infection (STI) worldwide, but current data concerning the prevalence of CT among women in Iran is scarce. Data regarding the frequency of CT infection among Iranian women can help to justify the implementation of a national CT screening program that can reduce the high morbidity associated with sequelae of CT infections by treating infected women. Endocervical secretions from 123 married women (20–55 years) with cervicitis were tested by a PCR-EIA method using primers to amplify a CT-specific plasmid. The digoxigenin-labeled amplicon was measured by hybridization to a biotin-labeled probe and a streptavidin-coated plate, followed by an enzyme-linked colorimetric analysis. Overall frequency of CT infection among women was 17% (21/123). The range of CT frequency among various age groups was 12–25%. The 31–40-year-age group comprised the majority (49%) of CT positive samples, followed by 20–30 year group (33%). Although the 20-to-30-year-old women reported the highest frequency of STI history, they had the lowest relative frequency of CT infection (12%). There is a high frequency of CT infection among women with cervicitis in Tehran, Iran, thus indicating a necessity to implement a routine CT screening program in the major cities of Iran and possibly nationwide. Identification of CT-infected women may prevent its spread, and thereby reduce the high morbidity associated with CT infections among women in Iran.

1. INTRODUCTION

Chlamydia trachomatis (CT) is the most common cause of bacterial sexually transmitted infections (STI), with millions of cases reported annually throughout the world [1]. Most genital CT infections in women are asymptomatic; however, chlamydial infections can commonly lead to sequelae complications such as pelvic inflammatory disease (PID), an increased risk of ectopic pregnancy, and infertility [2, 3]. Early diagnosis is essential for the timely treatment of CT-infected women to prevent the development of sequelae and preventing the transmission of CT to susceptible individuals. National screening programs that identify and treat CT-infected women have been shown to reduce the rates of CT infections and the morbidity associated with CT infections [4, 5]. Regrettably, nationwide STI surveillance programs are absent in Iran, and a majority of women have inadequate access to reproductive health services or STI clinics. Consequently, information concerning the prevalence of CT among women in Iran is scarce. Current data regarding CT infection from a

region is essential for controlling its spread and for helping assess the impact of CT on the reproductive health of women. In this small study, we report the incidence of CT infection among women with cervicitis in Tehran, Iran.

2. MATERIALS AND METHODS

2.1. Patients and specimens

A total of 123 married women (aged 20–55 years) with symptomatic cervicitis participated in this case series study. Participants visited the obstetrics and gynecology section of Mirza Kouchek Khan Hospital in Tehran, Iran, between December 2004 to June 2005, primarily complaining of pelvic pain and/or vaginal discharge. All women who received antibiotic treatment within three weeks prior to their visit were excluded from our study. Consenting participants completed a questionnaire before cervical examination in which they were asked for demographic data and any STI history (i.e., self-reported). Cervical examination included the evaluation

for the presence of mucopurulent endocervical discharge, friability, and ectropin. After removing cervical mucus, samples of the endocervical canal secretions were collected on two cotton swabs, which were washed in 500 μ L of phosphate buffered saline and the fluid was stored at -20°C . DNA was extracted from 100 μ L of the endocervical sample fluid using the DIAtom Prep100 kit (IsoGene Inc., Moscow, Russia) and was stored at -20°C until used.

2.2. PCR amplification

This method has been described in detail elsewhere [6]. Briefly, a 377 bp fragment of a cryptic plasmid (specific to *C. trachomatis*) was amplified through 30 cycles (pre-denaturation step at 94°C 3.5 min, denaturation at 94°C 30 s, primer annealing at 52°C , and 30 s primer extension at 72°C 3 min) in 25 μ L PCR reaction buffer (consisting of 10 mmol/L TRIS, pH 8.3, 50 mmol/L KCl, 2.5 mmol/L MgCl_2 , and 0.01% gelatin); 0.2 mmol/L each of dATP, dGTP, dCTP, and dTTP; 2.5U *Taq* DNA polymerase; and 0.5 μ mol/L primers for conserved plasmid nucleotide sequences of *C. trachomatis* (Table 1).

2.3. PCR-EIA

The amplicon was measured by the detection of digoxigenin-labeled *C. trachomatis* PCR products in a microtiter-based enzyme immunoassay (PCR-EIA). Briefly, 10 μ L of amplicon was denatured with 20 μ L NaOH and incubated at room temperature (RT), and after 10 min, 220 μ L of hybridization buffer containing 10 pmol of the 5' end biotin-labeled CT-specific internal oligonucleotide probe (complementary to the primers) was added. The amplicon was hybridized in solution for 30 min at 54°C , and the mixture was added to a streptavidin-coated 96-well microtiter plate. Using a hybridization-based EIA (Roche Diagnostics, Mannheim, Germany), 200 μ L of 1 : 100 diluted peroxidase-conjugated antidigoxigenin IgG was added to each well, incubated for 30 min at 37°C . After the wash (5X), 200 μ L of the ABTS substrate solution was added, and the plate was incubated for 30 min at 37°C . The optical density (OD) of the samples was measured by spectrophotometry at 405 nm absorbance (reference filter: 492 nm). The PCR-EIA run was considered valid if (–) control OD values were <0.1 , and the PCR positive control value was >1.0 . The background OD value was 0.055, calculated as the mean of all (–) control samples plus 3 standard deviations (SD). A sample was considered (+) if its OD value was greater than the background cutoff value by threefold (i.e., 0.165). The mean OD value of CT positive control samples was 1.81 ± 0.789 .

3. RESULTS

Table 2 shows the rates of *C. trachomatis* infection among all four age groups of married women studied. Overall, 17% (21/123) of the specimens were positive for chlamydial DNA by the PCR-EIA assay. The CT infection frequency rate ranged from 12% to 25% among the patient age groups

TABLE 1: The DNA sequence of PCR primers and the probe used for detection of *C. trachomatis* by PCR-EIA assay.

Primer/probe name	DNA sequence (5' → 3')
BP1 (sense)	AACCGTTTTTAATAGTGGCA
BP2 (antisense)	TTCTGGCCAAGAATTATCC
BP3 (probe)	AGCAGCTGCGAAAAAGAGAC

(Table 2). Although the 31–40-year group represented 35% of the samples, this age group comprised a marked 49% (10/21) of CT positive samples. Conversely, the 20–30-year group, which represented about half the patients investigated, comprised only 33% (7/21) of the *C. trachomatis* positive samples. Interestingly, when these two groups were combined, the 20–40-year group represented 81% of women in this study, and their samples comprised 81% of all CT positive specimens, as well.

On the other hand, as Table 2 demonstrates, when the CT positive samples were adjusted for the number of specimens within each age group of women, the highest rate of CT positive samples (25%) was from the >51 -year-old women (1/4), however, the >51 -year-age group represented $<1\%$ of the samples studied. The 31–40 age group showed the second highest rate of CT infection with 23.3% (10/43), followed by the 41–50-year-old women comprising 15.8% (3/19) of CT positive samples.

Overall, 29% (36/123) of patients reported to have STI history. Interestingly, even though the youngest group (20–30 years) in our study reported the highest adjusted rate of STI history 35% (20/57), these women showed the lowest (12.3%) adjusted frequency of CT infection with (Table 2). With the exception of the 31–40-year-age group, among all age groups investigated, the proportion of women who admitted to having a history of STI was higher than that of those with genital CT infection (Table 2).

4. DISCUSSION

The 17% frequency rate of CT genital infections among married women in Iran is in contrast with the 7% rate previously reported from Iran in the early 1980s [7]. Although the patients in neither study are representative of the general population, including asymptomatic women, the current CT infection rate is higher than the 4–11% prevalence rates reported from Slovenia, Holland, Colombia, Canada, and the United States [5, 8–11]. The difference in genital CT infection rate among women in this study as compared to recent reports from Tehran [6, 12] may relate to the improved sensitivity of the PCR-EIA employed, as well as the differences in the type of patients and specimens analyzed.

Our findings highlight the need for routine CT screening, particularly among Iranian women aged <40 years, for early detection of genital chlamydial infection to reduce the morbidity associated with sequelae. It has been shown that the level of chlamydial cervicitis decreases quickly in countries where routine screening for CT has become mandatory [4]. Early diagnosis and appropriate treatment of chlamydial

TABLE 2: Frequency of *C. trachomatis* infection among women with cervicitis according to their age groups. (CT = *C. trachomatis*; STI = sexually transmitted infection.)

Age group (year)	Patient number (%)	(+) STI history number (%)	(+) CT number	% (+) CT (of total*)	% (+) CT (within each age group)
20–30	57 (47)	20 (16)	7	5.7%	12.3%
31–40	43 (35)	8 (7)	10	8.1%	23.3%
41–50	19 (15)	4 (3)	3	2.4%	15.8%

cervicitis among the younger women will help to prevent transmission of *C. trachomatis* to susceptible individuals and avoid severe complications that eventually develop in older women. Initially, screening programs may focus on patients visiting the infertility or STI clinics in large cities of Iran and can later expand to cover the symptomatic as well as asymptomatic CT-infected women throughout the country.

We acknowledge that our results would have been enhanced by a larger sample size as well as additional demographic and behavioral data (i.e., socioeconomic status) which would have allowed for advanced data analysis. Overcoming obstacles, which hinder studies like ours, such as the social stigma associated with patients visiting the STD clinics plus increasing the number of women's health centers offering diagnostic services for management of CT cervicitis can make a significant impact on women's reproductive health by preventing the long-term sequelae associated with PID [3, 13]. Nevertheless, our data lends support to implementing a nationwide screening program to identify and treat Iranian women with CT infections using sensitive methods. Other countries have shown that such programs are cost-effective and can lead to reduced morbidity associated with chlamydial infections [14]. Since most women with genital chlamydial infection are asymptomatic, and our study did not include this group of women, the rate of CT infection might be higher than 17% among women in Tehran. Therefore, improving the status of women's reproductive health care services is well justified in the large cities of Iran.

To the best of our knowledge, this is the first report from Iran that provides current data regarding frequency of genital CT infection among married Iranian women with cervicitis, and may be particularly helpful to physicians treating such patients in Iran, where the quality of women's health care requires drastic improvement.

In conclusion, the high frequency of CT genital infections among married women in Iran warrants a comprehensive study to screen a large number of women suffering from chlamydial infection, thus allowing for better estimates of the real magnitude of the reservoir of asymptomatic CT infections among Iranian women. In light of studies that have shown chlamydial genital infections which can serve as biological cofactors for the transmission of the human immunodeficiency virus (HIV) [15–17], and a cofactor in human papillomavirus (HPV) infection [18], screening pro-

grams for genital chlamydial infections may reduce the morbidity associated with other sexual-transmitted pathogens in women and help decrease the cost of reproductive as well as general health care in developing countries, such as Iran.

ACKNOWLEDGMENTS

The authors of this manuscript wish to thank the women who kindly participated in this study. Also, we would like to express gratitude to the medical personnel at the obstetrics and gynecology section of Mirza Koucheh Khan Hospital in Tehran, Iran. This research investigation was financially supported in part by a grant from the Research Council of Tehran University of Medical Sciences (Grant no. 132/9155).
