Effect of Metal Chelators on $\gamma$-Secretase Indicates That Calcium and Magnesium Ions Facilitate Cleavage of Alzheimer Amyloid Precursor Substrate

Gamma-secretase is involved in the production of A$\beta$ amyloid peptides. It cleaves the transmembrane domain of the amyloid precursor protein (APP) at alternative sites to produce A$\beta$ and the APP intracellular domain (AICD). Metal ions play an important role in A$\beta$ aggregation and metabolism, thus metal chelators and ligands represent potential therapeutic agents for AD treatment.

A direct effect of metal chelators on $\gamma$-secretase has not yet been investigated. The authors used an in vitro $\gamma$-secretase assay consisting of cleavage of APP C100-3XFLAG by endogenous $\gamma$-secretase from rodent brains and human neuroblastoma SH-SY5Y, and detected AICD production by western blotting. Adding metalloprotease inhibitors to the reaction showed that clioquinol, phosphoramidon, and zinc metalloprotease inhibitors had no significant effect on $\gamma$-secretase activity. In contrast, phenanthrole, EDTA, and EGTA markedly decreased $\gamma$-secretase activity that could be restored by adding back calcium and magnesium ions.

1. Introduction

Gamma-secretase is a key protease activity involved in the production of Alzheimer’s disease A$\beta$ amyloid peptides and in regulated intramembrane processing of a subset of membrane receptors, including Notch (reviewed in [1]). A$\beta$ is proteolytically derived from the type I integral amyloid precursor protein (APP) [2] by two sequential cleavages. Shedding of the large APP ectodomain by $\beta$-secretase ($\beta$-APP cleaving enzyme1, BACE1) [3] produces a 99 amino acid membrane-tethered stub ($\beta$-secretase generated APP C-terminal fragment, $\beta$-CTF, or C99) that is further processed by $\gamma$-secretase to liberate A$\beta$ peptides in the extracellular/luminal space. $\gamma$-Secretase cleaves the transmembrane domain of APP at multiple sites. Cleavage at the $\epsilon$-site [4], at position 49-50 according to numbering from A$\beta$ N-terminus mediates the cytosolic release of APP intracellular domain (AICD) together with its binding partners and regulates their nuclear translocation [5]. Further cleavages at the $\zeta$(46-47) and $\gamma$(40-41) sites generate A$\beta_{40}$ [6]. Pathogenic mutations in APP or in the presenilins result in shifting of $\epsilon$-cleavage to the (48-49) site and production of A$\beta_{42}$ [7]. APP also undergoes ectodomain shedding by cleavage within the A$\beta$ domain by $\alpha$-secretase, in a nonamyloidogenic cellular pathway, followed by $\gamma$-secretase processing of the corresponding membrane stub (C83) to release AICD and a p3 fragment (reviewed in [8]).

$\gamma$-Secretase activity is contained within high molecular complexes formed by assembly of four integral membrane proteins, presenilin, nicastrin, Aph-1, and Pen-2 [9]. Gene knockout experiments [10] and mutation of two conserved aspartates [11] have revealed that the presenilins,
either PS1 or PS2, are membrane proteases and constitute the catalytic subunits of γ-secretase complexes.

The mechanism of γ-secretase and its modulation are yet to be elucidated. We aimed to investigate the effect of metal chelators on γ-secretase activity in vitro. Indeed, biometals and metalloenzymes play an important role in the metabolism of APP and Aβ. APP itself comprises two zinc/copper binding sites, one of them located within the Aβ sequence [12–14]. Although the precise function of APP remains unclear, a wealth of experimental evidence indicates that it plays a role in copper homeostasis [15]. The reduction of Cu²⁺ to Cu⁺ by APP is accompanied by the production of hydrogen peroxide resulting in oxidative stress [16]. Also, metal ions, particularly copper, mediate Aβ oligomerization and toxicity [17], therefore metal chelators and ionophores are currently being evaluated as drug candidates for AD treatment (reviewed in [18]). To support the merit of this therapeutic approach, the copper chelator clioquinol (CQ) has been shown to reduce Aβ deposition in the brain of an AD transgenic mouse model [19].

Metals are also implicated in Aβ clearance as the enzymes that metabolize Aβ peptides are zinc-dependent (for a complete review, see [20]), in particular the insulin-degrading enzyme (IDE) [21–24], neprilysin (NEP) [25–27], and the matrix-metalloproteinases MMP2 and MMP9 [28–30]. Secretase processing of APP is also influenced by metal ions since the α-secretase enzymes belong to the family of ADAM proteases, which are zinc-metalloproteases [31], and the β-secretase enzyme; BACE1 comprises a copper-binding site within its cytoplasmic tail, which may regulate its enzymatic activity [32].

In this paper, we have evaluated the direct effects of metal chelators on γ-secretase in an in vitro assay using endogenous enzyme extracted from guinea pig and mouse brains, or from human neuroblastoma SH-SY5Y cells, together with C100-3XFLAG substrate, an analogue of APP β-CTF.

2. Materials and Methods

2.1. Materials and Reagents. Adenosine 5'-triphosphate disodium salt (ATP), ethylene glycol-bis[2-aminoethyl ether]-N,N,N',N'-tetraacetic acid (EGTA), glycerol, 5-chloro7-iodo-8-hydroxyquinoline (clioquinol or CQ), D,L-thiophan, P-2714 protease inhibitor cocktail, [3-(3-cholamidopropyl)dimethylammonio]-1-propanesulfonate (CHAPSO), M2 monoclonal antibody, and anti-FLAG M2-agarose were purchased from Sigma-Aldrich (Sydney, Australia). L-685,458 inhibitor was obtained from Dr. Mark Shearman (Merck, Sharpe, and Dohme). L-685,458 inhibitor was obtained from Dr. Mark Shearman (Merck, Sharpe, and Dohme).

2.2. C100-3XFLAG Preparation and Purification. E. Coli transformed with the C100-3XFLAG vector were grown and induced for C100-3XFLAG expression as described before [33]. The cells were harvested, resuspended in 50 mM HEPES, 5 mM MgCl₂, 5 mM CaCl₂, 150 mM KCl, and pH 7.4, supplemented with 1% (w/v) P-2714 (Sigma) protease inhibitor cocktail, and disrupted by sonication. Membranes were isolated by centrifugation for 1 hour at 100,000 g, and were resuspended in homogenisation buffer containing 1% (v/v) CHAPSO, using a Dounce homogenizer, followed by repeated passages through syringe needles of decreasing bore size. The resultant fine suspension was incubated for 1 hour at 4°C, with end-over-end rocking, then centrifuged at 18,000 g for 1 hour at 4°C, and the supernatant containing the solubilized proteins was brought up to 10% glycerol (v/v). C100-3FLAG was affinity-purified on anti-FLAG M2-agarose column and the purified substrate was stored as aliquots at −80°C.

2.3. Preparation of γ-Secretase Activity. All steps were carried out on ice and the centrifugation steps done at 4°C. Guinea pigs and mouse (C57Bl6) brains were obtained from the Animal Facility of the University of Melbourne Department of Pathology as secondary tissue usage of excess animals. Homogenates from whole brains, minus cerebellum, were prepared as described previously [33]. The crude tissue homogenate prepared in 20 mM HEPES, pH 7.4, containing 250 mM sucrose, and 1% protease inhibitor cocktail (with no pepstatin), was centrifuged at 3,000 g for 30 minutes to remove cellular debris. The supernatant was collected and centrifuged further at 100,000 g for 1 hour in a L8-80M ultracentrifuge equipped with a TI70.1 rotor (Beckman-Coulter). The pellet was washed with 20 mM HEPES, 150 mM KCl, and pH 7.4, and resuspended in the same buffer plus 1% (v/v) CHAPSO, with mixing on a rotating platform for 1 hour, at 4°C. CHAPSO-extracted membranes were removed by centrifugation at 18,000 g for 20 minutes. The supernatant, containing solubilized γ-secretase, was brought up to 10% glycerol (v/v), and stored as aliquots at −80°C.

Alternatively, SH-SY5Y cells were resuspended in 20 mM HEPES, 80 mM KCl, and pH 7.3, supplemented with 1% protease inhibitor cocktail, and homogenized by repeated passages through a 25-gauge needle. The cell homogenate was centrifuged at 1,000 g for 20 min to remove nuclei and cell debris. The resultant supernatant was collected and centrifuged for 1 hour at 100,000 g. The sediment pellet was extracted with 1% CHAPSO.

2.4. Gamma-Secretase Assays. Purified recombinant substrate (~1.5 μM) and CHAPSO-solubilized membranes (3 μg of guinea pig or mouse brain preparation, or 15 μg of SH-SY5Y membrane extract) were incubated for 4 to 18 hours at 37°C in presence of ATP (1.25 mM) and a mixture of phosphotidyl-ethanolamine (PE) and phosphatidylcholine (PC) (50 ng each; Sigma-Aldrich) in a final reaction volume of 20 μL of 20 mM HEPES (pH 7.4) and 0.5% CHAPSO, plus either 2 mM EDTA (buffer E) or 5 mM CaCl₂, 5 mM MgCl₂ and 150 mM KCl (buffer A). Inhibitors were prepared as stocks in DMSO and used at dilutions so that DMSO concentration in incubations was no more than 2.5%. Incubations were terminated by adding Laemmli SDS sample buffer and heating at 95°C for 5 minutes. The samples were electrophoresed for 5 hours on
Tris-tricine gels (two-layer, 10–15% acrylamide discontinuous gradient) using a miniPROTEAN 3 system (Bio-Rad) followed by electrophoresis to nitrocellulose (Trans-blot, Bio-Rad). The blots were boiled in phosphate buffer saline, pH 7.4 (PBS) for 3 min prior to blocking for 1 hour with 0.5% casein in PBS and probing with primary antibody for 2 hours. The blots were developed with the Super Signal West Dura kit (Pierce, Rockford, IL) and exposed to a GeneGnome digital imaging system (Syngene, Cambridge, UK). Data were analysed using GeneTools software (Syngene). γ-Secrease activity was expressed as the sum of C100 plus AICD signals after subtracting blank values. Aβ was quantified by DELFIA as described before [34]. In brief, plates were coated with mouse monoclonal antibody G210 (specific for Aβ40) and developed with biotinylated WO2 (anti-Aβ 1–16). Bound antibody was detected with streptavidin-labeled Europium (Perkin Elmer, Inc, Melbourne, Victoria). Results were calculated from a standard curve obtained with Aβ40 synthetic peptide.

2.5. BN-PAGE Analysis. SH-SY5Y membrane extract (0.5% CHAPSO), prepared as described above, was mixed with an equal volume of 20 mM HEPES (pH 7.4) containing 0.5% CHAPSO plus one of the following, 2 mM EDTA, 2 mM EGTA, 5 mM MgCl2, or 5 mM CaCl2, and incubated for 18 hours at 19°C. BN-PAGE sample buffer was added and the samples resolved on 3–8% NuPAGE Tris-acetate gels (Invitrogen) as described previously [35].

2.6. Size-Exclusion Chromatography. SH-SY5Y membrane extracts (diluted to 0.5% CHAPSO) prepared as for BN-PAGE were fractionated on a Superose-6 column (GE Healthcare) equilibrated in 20 mM HEPES, 150 mM KCl buffer, and pH 7.3 and eluted at a flow rate of 0.5 mL/min. 0.5 mL fractions were collected and analysed by western blotting with 98/1 antibody [36].

3. Results

3.1. In Vitro γ-Secrease Assay. C100 substrate, expressed in E. coli, is based on the human APP C-terminal sequence, which corresponds to the C-terminal fragment produced by β-secretase cleavage of APP (β-CTF, the direct precursor to Aβ) plus N-terminal Met196. C100 is expressed with a 3XFLAG C-terminal tag to improve solubility, stability, and detection of AICD [33]. Incubations of C100-3XFLAG with γ-secretase preparations from guinea pig brain membranes produced a 10 kDa C-terminal fragment that was inhibited in a dose-response manner by two specific γ-secretase inhibitors, L-685,458 [37], and DAPT [38] (Figure 1(a)). AICD production was time dependent (Figure 1(b)). Detection of Aβ with WO2 shows an increased production between 2 and 4 hours but the results could not be quantified due to high background and merging of the bands between the lanes.

The effects of phospholipids and ATP were tested to further validate the AICD detection assay and optimize conditions. Adding phospholipids (PC and PE, 2.5 μg/mL each) enhanced the production of AICD (Figure 1(c)), a result consistent with reports by others [39, 40]. Adding ATP (1.25 mM) to the γ-secretase/APP substrate reaction was also found to cause an average 1.6-fold increase of AICD production (Figures 1(d) and 1(e)), corroborating the report by Fraering et al. [41] who used recombinant γ-secretase solubilized from membranes of cells overexpressing the γ-secretase components. The positive effect of ATP was also obtained using γ-secretase preparations from SH-SY5Y-membranes (data not shown).

3.2. Effect of Zinc and Copper Chelators on γ-Secrease Activity. The effect of metal ion chelators and metalloprotease inhibitors on γ-secretase was evaluated using various compounds (Figures 2(a) and 2(b)). The zinc chelators, thiorphan and phosphoramidon, and the hydroxamate inhibitor ilomastat, which is an inhibitor of a-secretase, were all assayed at 250 nM, a concentration sufficient to completely inhibit their target metalloprotease activities in cells and tissues. There was no significant effect of these compounds in the γ-secretase assay, although thiorphan showed a trend for an increase in AICD signal. Thiorphan, an inhibitor of neprilysin, which might be present in the assay as it is associated with brain membranes. The modest decrease in γ-secretase activity in the presence of the copper chelator cloquiolin was not statistically significant. In contrast a 65% decrease in AICD production (P = .024; N = 3) was observed in the presence of phenanthroline (5 mM), suggesting that some metal ions facilitate γ-secretase activity.

3.3. Metal Chelators of Broad Specificity Decrease γ-Secrease Activity. The reduction of activity in the presence of phenanthroline led us to test the effect of EDTA, another chelator of broad specificity. Indeed, reports in the literature indicate the use of alternative buffers for in vitro γ-secretase assays. Notably, these involve the use of buffers that either contain EDTA [41, 42], or that are supplemented with Ca2+ and Mg2+ [39, 40, 43–45]. Therefore, we compared both conditions in our assay (Figures 3(a) and 3(b)). In the presence of EDTA, AICD production was 28% of that in the presence of buffer with Ca2+ and Mg2+ (P = .0002, N = 5). Measurement of Aβ40 production by a sandwich ELISA (Figure 3(c)) showed that 0.035 ± 0.01 ng/mL Aβ40 was produced in the presence of Ca2+ and Mg2+ whereas 0.011 ± 0.004 ng/mL was produced in the presence of EDTA, further supporting that Ca2+ and Mg2+ ions facilitate the processing of C100 by γ-secretase. Similar results were obtained when using solubilised SH-SY5Y membranes as the source of γ-secretase, with AICD production in the presence of EDTA being 30% to that in the presence of Ca2+ and Mg2+ (Figures 3(d) and 3(e)). Comparing incubations with and without Ca2+ and Mg2+ showed that the addition of these metal ions ameliorates γ-secretase activity by 1.65-fold (P = .02, N = 3) (Figures 3(d) and 3(e)). These data are consistent with those obtained with phenanthroline, and suggest that adding Ca2+ and Mg2+ metal ions facilitate γ-secretase cleavage of APP substrate.
3.4. Ca²⁺ and Mg²⁺ Facilitate γ-Secretase Activity. To define which of Ca²⁺ and Mg²⁺ ions were important for γ-secretase activity, we tested the effect of EGTA that has much greater affinity for calcium than magnesium. In the reactions carried out with guinea pig or mouse γ-secretase activity, there were similar levels of AICD produced in the presence of EGTA than in the presence of EDTA (Figures 4(a) and 4(b)), suggesting that Ca²⁺ ions are required for the enhancement of γ-secretase activity. When, reactions were prepared in the presence of 2 mM EDTA and increasing concentrations of CaCl₂ or MgCl₂ were added, both Ca and Mg ions individually restored AICD production to levels achieved with the Ca and Mg buffer (Figure 4(c)). However, when Mg ions were absent in the reaction, adding 3 mM calcium resulted in precipitation of the C100 substrate. Therefore, both calcium and magnesium are required for optimal assay conditions.
Figure 2: Effect of metalloprotease inhibitors, and metal chelators on \( \gamma \)-secretase. Chelators and inhibitors were added as DMSO solutions (final DMSO concentration 2.5%) to the guinea pig brain \( \gamma \)-secretase/C100-3XFLAG reactions. (a) Representative western blot of \( \gamma \)-secretase assay in the presence of various inhibitors. Phpm, phosphoramidon; Ilmst, ilomastat; Pht, phenanthroline; CQ, clioquinol; \( \gamma \)-inh, L-685,458, used at 10 nM (lane 6) and 100 nM (lane 7). (b) Effect of metalloprotease inhibitors on the \( \gamma \)-secretase assay. Activity is expressed as the % of substrate converted into AICD, as determined from band density analysis with GeneTools software. The error bars represent SEM. Inhibitor concentrations were selected as follows: thiorphan, 250 nM; phosphoramidon, 25 \( \mu \)M; ilomastat, 250 nM; phenanthroline, 5 mM; clioquinol, 100 \( \mu \)M.

Figure 3: Effect of EDTA and phenanthroline on \( \gamma \)-secretase activity. (a) Guinea pig \( \gamma \)-secretase activity was assayed on C100-3XFLAG in alternate buffer conditions (2 mM EDTA or 3 mM CaCl\(_2\) and 3 mM MgCl\(_2\)). (b) Quantitative analysis of five separate experiments shows AICD production in the presence of EDTA was 28% of that produced in the presence of CaCl\(_2\) and MgCl\(_2\). (c) Quantitative analysis of A\( \beta \)40 by sandwich DELFIA shows that A\( \beta \) production in the presence of EDTA is lower than in the presence of CaCl\(_2\) and MgCl\(_2\). (d) \( \gamma \)-Secretase activity extracted from SH-SY5Y membranes was assayed in buffer conditions as indicated. Phenanthroline (Pht) concentration was 5 mM. L-685,458 was 0.5 \( \mu \)M. (e) Quantitative analysis of three blots corresponding to assays carried out as in (d) The error bars represent SEM.
3.5. Calcium and Magnesium Ions Stabilize a High Molecular Weight γ-Secretase Complex. To determine if calcium and magnesium ions had an effect on the size and stability of γ-secretase complexes, SH-SY5Y membrane-extracts diluted with 20 mM HEPES, and 150 mM KCl (pH 7.3) to a CHAPSO concentration of 0.5% were incubated in the presence of either 2 mM EDTA, 2 mM MgCl₂, or 2 mM CaCl₂, and analyzed by BN-PAGE and western blotting for PS1 (Figure 5(a)). In HEPES buffer, with no added calcium or magnesium, and in the presence of EDTA or EGTA, PS1 was found mostly associated with a 350 kDa complex, and a minor amount with a 450 kDa complex. In the incubations with Mg²⁺, with or without ATP, presenilin was found associated with a ∼450 kDa complex and also, in a small proportion with a 1,000 kDa complex. In the presence of Ca²⁺, PS1 was found mostly associated with the ∼450 kDa complex. These data suggest that Ca²⁺ and Mg²⁺ ions contribute to stabilization of γ-secretase complexes, possibly in association with binding partners. Further analysis of PS1 γ-secretase complex sizes by gel filtration on a Superose-6 column (Figure 5(b)) showed that, in the presence of Mg²⁺ ions, most PS1 immunoreactivity is recovered in a symmetrical peak in fractions corresponding to ∼1,000 kDa. In the presence of EDTA, the peak of PS1 immunoreactivity was less sharp and broader, suggesting decreased complex stability.

4. Discussion

Biometal ions and metalloenzymes play an important role in the metabolism of APP and Aβ, and the pharmacomodulation of copper levels in the brain represents a promising therapeutic approach to treat AD [18]. Little is known about the effect of metal ions on γ-secretase activity. We found that the copper-selective chelator, clioquinol did not significantly alter AICD production, suggesting that copper is not directly involved in γ-secretase cleavage of the APP substrate. This finding is consistent with our previous report that CQ does not alter production of Aβ in CHO-APP cells [28]. The zinc chelators, thiorphan and phosphoramidon, and the α-secretase inhibitor, ilomastat, showed no significant effect on the γ-secretase reaction.
In contrast, γ-secretase activity was reduced in the presence of EDTA and phenanthroline. EGTA had an effect comparable to that of EDTA, indicating the possible involvement of calcium ions in the assay. Adding back calcium or magnesium to incubations carried out in the presence of EDTA showed that both enhanced AICD production.

In vitro γ-secretase assays described in the literature are carried out in alternative conditions, either in buffers containing EDTA [42, 46], or in buffers supplemented with Ca2+ and Mg2+ [39, 40, 43–45]. The γ-secretase assays based on Aβ detection are usually carried out in the presence of EDTA, probably to prevent metal-dependent self-aggregation of the peptide that would interfere with antibody capture in immunoassays, whereas the assays based on western blot detection of AICD have been preferably carried out in the presence of calcium and magnesium ions. Parallel incubations in EDTA buffer and in buffer supplemented with CaCl2, and MgCl2, revealed that AICD production was lower by 70–78% in the presence of EDTA than in the presence of Ca2+ and Mg2+. Aβ levels, detected by ELISA (Figure 3(c)), were also higher in the presence of Ca2+ and Mg2+, suggesting that the same effect of these ions applies to Aβ and AICD production.

To investigate whether calcium and magnesium ions influence the stability of γ-secretase complex, we used both BN-PAGE analysis and gel filtration. These techniques have been previously used to demonstrate that γ-secretase activity associates with high molecular weight complexes [44, 47]. In the present paper, fractionation of γ-secretase preparations by BN-PAGE suggested that Ca2+ and Mg2+ ions stabilized association of PS1 with high molecular weight complexes of 1,000 and 450 kDa, compared to ∼350 kDa complexes observed in the presence of EDTA and EGTA. When incubations with EDTA and without Ca2+ or Mg2+ were treated with a cross-linker prior to BN-PAGE, the ∼1,000 kDa complex was also detected in these incubations (data not shown), suggesting that this 1,000 kDa form was normally present but was less stable through electrophoresis in the absence of Ca2+ and Mg2+ ions, and without cross-linking. Size-exclusion chromatography also suggested that Mg2+ ions stabilized HMW γ-secretase complexes. Although only the four subunits, PS, nicastrin, Aph1, and Pen-2 are required for γ-secretase activity and formation of a complex of ∼350 kDa, many proteins and other molecules such as phospholipid and ATP have also been shown to associate with γ-secretase complexes and to modulate their activity [48]. For instance, a recent paper reports that PION protein modulates the specificity of γ-secretase towards APP [49]. Three-dimensional reconstruction of the γ-secretase structure from electron micrographs of purified γ-secretase has shown the presence of two weak-density lateral regions [50] and it is tempting to speculate that these could accommodate metal ions. Magnesium ions form complexes with ATP and could mediate the interaction between ATP and presenilin [40]. Alternatively, calcium and magnesium...
may play an accessory role by ordering membrane phospholipids. Indeed, it has been reported that substituting EDTA-containing buffer for a buffer supplemented with calcium and magnesium help stabilize and isolate lipid rafts [51]. γ-Secretase components associate with lipid rafts, cholesterol-rich membrane regions where high γ-secretase-specific activity has been detected [52, 53]. Furthermore, experimental evidence indicates that lipids are important for γ-secretase activity [44]. Therefore, calcium and magnesium may facilitate movement of membrane domains and substrate access to the γ-secretase active site. Structural analysis by solid-state NMR and electron microscopy has demonstrated that cations modulate phospholipid bicelle size and that MgCl₂ and CaCl₂ stabilize large diameter (500 Å) bicelle discs [54]. Thus, the increase in molecular mass of γ-secretase that was observed when adding divalent cations may be consistent with the association of a larger number of detergent and phospholipid molecules with the γ-secretase complex.

Considering that Aβ has been shown to form membrane pores and disrupt neuronal calcium homeostasis by increasing Ca²⁺ influx [55], elevated Aβ could contribute to increased intraneuronal [Ca²⁺] that might in turn increase γ-secretase activity and Aβ production. Thus, it will be important to clarify how calcium and magnesium tune γ-secretase activity as this may have potential implications in AD pathogenesis.

5. Conclusions

Our study indicates that copper and zinc chelators have no direct effect on γ-secretase activity in vitro. It also demonstrates that chelators of broad specificity decrease cleavage of APP C100 substrate. Furthermore, it shows that Ca²⁺ and Mg²⁺ ions facilitate AICD production and contribute to stabilizing HMW γ-secretase complexes. This finding suggests that Ca²⁺ and Mg²⁺ mediate molecular associations that modulate γ-secretase activity.

Abbreviations

Aβ: amyloid-β peptide
AICD: APP intracellular domain
APP: amyloid-β precursor protein
ATP: adenosine 5′-triphosphate
BN-PAGE: blue native polyacrylamide gel electrophoresis
