This paper describes the design and development of a triband with circularly polarized quasi-Yagi antenna for ka-band and short range wireless communications applications. The proposed antenna consists of an integrated balun-fed printed dipole, parasitic folded dipole and a short strip, and a modified ground plane. The antenna structure, together with the parasitic elements, is designed to achieve circular polarization and triband operating at resonant frequencies of 13.5 GHz, 30 GHz, and 60 GHz. Antenna design was first simulated using HFSS ver.14, and the obtained results were compared with experimental measurements on a prototype developed on a single printed circuit board. Achieved characteristics include -10 dB impedance bandwidth at the desired bands, circular polarization axial ratio $AR < 3$ dB, front to back ratio of 6 dB, gain value of about 4 dBi, and average radiation efficiency of 60%. The paper includes comparison between simulation and experimental results.

1. Introduction

Recently printed antennas have been commonly used in sensing and various communications and radar systems applications due to their low cost, low profile, and simple integration with transceiver systems. For example, microstrip arrays are highly desired for the broadcast satellite services (BSS) in the frequency band at 13.5 GHz [1]. Moreover, the unlicensed frequency bands in the 30 GHz and 60 GHz ranges are used for increased data rate of more than 1 Gb/s in WLAN (wireless local area network IEEE 802.11n) and WPAN (wireless personal area network) short range communication systems [2].

Some examples of printed antenna implementations illustrate specific and interesting particular solutions and show that they can be integrated with solid-state devices [3–5]. Of specific interest in this paper are those designs that are based on new shapes of Yagi-antenna implementation. Yagi-type antennas have several advantages over many other commonly used ones in portable communication systems [5–7]. First, the presence of the substrate provides mechanical support

for the antenna and planar transmission line compatibility. Second, the parasitic director element on the top plane simultaneously directs the antenna propagation towards the end-fire direction and acts as an impedance-matching parasitic element as well [8].

Development of antennas with circular polarization (CP) radiation patterns is also desirable in satellite communications systems and for portable wireless communications systems as they reduce multipath fading effects and provide flexibility in the orientation angles between transmitters and receivers. However, CP antennas reduce efficiency compared to linearly polarized antennas [7, 9]. Many CP antennas also have complex feeding networks and configurations and hence increase packaging cost and system sizes [10]. Nonetheless, various integrated CP antenna designs have been proposed for MM-wave applications and these designs were implemented in either multilayer or one-layer solutions [11].

Development of antennas with multiband radiation characteristics is yet another desirable and important feature. Various techniques of printed MM-wave antenna for dual band and circular polarization have been reported [12]. These

FIGURE 2: (a)–(c) Design steps of the proposed antenna and (d) $|S_{11}|$ result response at each step.

half of the effective wavelength ($\lambda_{\text{eff}}/4$) at 13.5 GHz, 30 GHz, and 60 GHz, respectively. The folded virtual dipole, T-shaped dipole, and parasitic strip act as the reflector, driver, and director of the proposed antenna, respectively. The optimized dimensions of the proposed antenna so as to provide good impedance matching at the desired frequency are given in Table 1.

The unequal arms lengths are between L_s , L_{s1} and L_R , L_{R1} , to be off center of the element axis L_D to cause 90° phase difference at 13.5 GHz, 30 GHz, and 60 GHz, respectively, without using any coupler network to provide circular polarization. This could be explained as by utilizing two different lengths of monopole arms, we realize a change in the electric current phases of the arms. Particularly, the radiated field is the submission of radiation of monopole arms currents. The arm with a length shorter than at resonance frequency

generates a wave with relative phase delay, whereas that with larger length generates a wave with relative phase advance. Taking advantage of this lead and lag of the antenna phases, the phase difference of 90° is tuned at this resonant frequency [8, 11, 12, 16–23].

The effects of L_s , L_R , L_D , and S_d on the antenna performance were examined by changing one parameter at a time and keeping the other parameters fixed as shown in Figure 3.

From Figure 3(a) it may be seen that as the length of T-dipole L_s is increased, from 1 to 3 mm with steps 1 mm, the fundamental resonant frequency decreased from 16 to 12 GHz. Moreover, L_s affects the lower resonant frequency at the higher band and reduces the resonant frequency from 56 to 53 GHz.

As for the folded dipole length L_R , simulation results show that as L_R is increased from 1 mm to 2 mm with step

FIGURE 3: (a)–(d) $|S_{11}|$ as function of L_s , L_R , L_D , and S_{dir} , respectively.

0.5 mm, the second resonant frequency is reduced from 33 to 28 GHz with slight effect on other resonant frequencies as shown in Figure 3(b).

The increase in the parasitic strip length L_D from 0.5 to 2 mm gives rise to a reduction in the highest frequency band from 58–75 GHz to 55–69 GHz without affecting the other resonant frequencies as shown in Figure 3(c). Moreover, the

separation between T-dipole and folded dipole S_{dir} independently affects the antenna resonant frequency response as shown in Figure 3(d).

The dimensions of the optimized antenna are shown in Table 1 where the length of L_{S1} is slightly increased compared to L_s by 0.2 mm, the length of L_{R1} is slightly increased from that of L_R by 0.15 mm, and the director element L_D is shifted

from the gap center of driver T-dipole by 0.5 mm. Figure 4 compares the measured and simulated axial ratios of the proposed antenna versus frequency at the maximum gain direction. Simulated results show that the antenna has an AR bandwidth of 5 GHz, 6 GHz, and 12 GHz at 13.5 GHz, 30 GHz, and 60 GHz, respectively. Measurements show that the AR bandwidth is close to 4 GHz and 8 GHz at 13.5 GHz, 30 GHz, and 60 GHz, respectively.

2.2. Antenna Performance. The performance of the proposed antenna at the three resonant frequencies was further simulated and studied. Results of the surface current distribution are shown in Figure 5 for each antenna resonant frequency. As it may be noted, for the band at 13.5 GHz, Figure 5(a) shows that the most current mainly flows on the printed T-shaped dipole and this contributes that the most radiation is mainly due to this element. For the second band at 30 GHz,

FIGURE 6: Simulated front to back ratio and gain of the proposed antenna.

Figure 5(b) shows that the current is mainly concentrated on the folded dipole, and this contributes the most radiation in this band. The same happens for the third band at 60 GHz, where current mainly concentrates on the parasitic element. As may be seen from Figure 6, simulated radiation profile (front to back ratio) is about 4.5 dB, 9 dB, and 7 dB while the simulated antenna gain is about 2.9 dBi, 7 dBi, and 6 dBi, at 13.5 GHz, 30 GHz, and 60 GHz.

3. Experimental Results and Discussion

The antenna was fabricated using mechanical etching technology with 0.1 mm accuracy on Rogers RO3035 substrate with a 0.13 and 0.017 mm dielectric and copper thickness. End launcher connector 1.85 mm is connected and an Anritsu 37397C vector network analyzer is used to measure the proposed antenna as shown in Figure 7(a). Comparison between measured and simulated reflection coefficient results is shown in Figure 7(b) with 5%, 10%, and 30% impedance bandwidth at 13.5, 30, and 60 GHz, respectively. As it may be seen, the $|S_{11}|$ bandwidth < -10 dB is almost the same between simulation and measurement, at lower frequencies, while at higher frequencies, the bands were shifted to lower frequency by about 3 GHz. This difference may be due to the capacitor loading between the proposed antenna and the feed-connector and may also be due to fabrication tolerance. The measured results were ended at 65 GHz due to the limited range of the VNA. The gain characteristics of the proposed mm wave antenna are evaluated by using method presented in [16–18]. The gain of the antenna under test is calculated by using Friis transmission:

$$\frac{|S_{21}|^2}{(1 - |S_{11}|^2)(1 - |S_{22}|^2)} = G_t G_r \left(\frac{\lambda}{4\pi R} \right)^2, \quad (1)$$

(a)

(b)

FIGURE 7: (a) Photo of fabricated antenna and (b) simulated and measured $|S_{11}|$ characteristics of the antenna.

where G_t, G_r are the gains of the transmitting and receiving antennas, respectively, while $|S_{21}|$, $|S_{11}|$, and $|S_{22}|$ are the transmission and reflection coefficient between a reference horn antenna having a known gain (Quin Star ≈ 21 dBi) and the reflection coefficient of the proposed antenna, respectively. λ is the operating wavelength and R the distance between the two antennas.

The measured and simulated radiation patterns and peak gain of the proposed antenna at frequencies 13.5 GHz, 30 GHz, and 60 GHz in the XZ and XY planes are shown in Table 2. This table also shows the fair agreement of measured and simulated patterns and gain. Discrepancy may be due to the reflective bodies of automobiles that caused fluctuations in readings; the movement and positioning of the coaxial cable altered patterns and mis-mounting of the antennas caused altered patterns. These errors increased especially at high frequencies. The large cross polarization radiation is assumed to be generated by the balun and the use of the large connector.

TABLE 2: Radiation patterns, EM: black lines, measurements: red lines, E_{Φ} : solid lines, and E_{Θ} : dash lines. Axis is shown in Figure 1.

FIGURE 8: The proposed antenna radiation efficiency versus frequency.

The antenna radiation efficiency was measured using the Wheeler cap method [19–21] at different operating resonant frequencies as shown in Figure 8. Results indicate that the larger end launcher connector comes on the expense of the radiation efficiency, which is reduced by 20% at the different operating frequencies. The radiation efficiency is almost 60% over the operating bands.

4. Conclusion

A new quasi-Yagi shaped antenna with multiband, circularly polarized, low profile, and low cost is presented. This antenna is particularly useful for satellite communications applications and short range wireless communications applications (WLAN/WPAN). The proposed antenna operates at three different bands 13.5 GHz, 30 GHz, and 60 GHz with 5%, 10%, and 30% impedance bandwidth, respectively. The reflection coefficient is better than -10 dB in the three bands and good agreement between measured and simulated gain and radiation pattern results were obtained. The front to back ratio is 6 dB with average gain of about 4 dBi and the average antenna radiation efficiency is about 60% over the antenna operating band. The 3 dB axial ratio is achieved at the three selected bands.

Conflict of Interests

The authors declare that there is no conflict of interests regarding the publication of this paper.
