Incidence of cardiovascular disease (CVD) is remarkably high among patients with chronic kidney disease (CKD), even in the early microalbuminuric stages with normal glomerular filtration rates. Proximal tubule cells (PTCs) mediate metabolism and urinary excretion of vasculotoxic substances via apical and basolateral receptors and transporters. These cells also retrieve vasculoprotective substances from circulation or synthesize them for release into the circulation. PTCs are also involved in the uptake of sodium and phosphate, which are critical for hemodynamic regulation and maintaining the mineral balance, respectively. Dysregulation of PTC functions in CKD is likely to be associated with the development of CVD and is linked to the progression to end-stage renal disease. In particular, PTC dysfunction occurs early in diabetic nephropathy, a leading cause of CKD. It is therefore important to elucidate the mechanisms of PTC dysfunction to develop therapeutic strategies for treating cardiorenal syndrome in diabetes.

1. Introduction

Chronic kidney disease (CKD) is a worldwide public health problem, and the incidence of end-stage renal disease (ESRD) with poor outcomes and associated high costs is increasing. Patients with CKD are also at high risk of developing cardiovascular disease (CVD). It is therefore important to elucidate the pathogenesis of CKD and the mechanisms underlying its role in the development of CVD.

Albuminuria/proteinuria is a distinctive clinical sign in patients with CKD. Although a decrease in glomerular filtration rate (GFR) correlates with an increase in incidence of CVD, patients showing normal GFR with even mild albuminuria/proteinuria are also at risk of developing CVD [1, 2]. The link between albuminuria/proteinuria and CVD has generally been attributed to vascular endothelial injury associated with the development of atherosclerosis. However, endothelial injury may not only be a cause of CKD, but also a consequence of the disease. In addition, the vascular pathology of CKD is characterized by medial layer calcification that may be mediated by calcium-phosphate dysregulation [3]. Therefore, to clarify the mechanisms of CVD in patients with CKD, it is important to investigate the renal factors that cause albuminuria/proteinuria and those that are involved in the induction of vascular endothelial injury and calcification.

The aim of this paper is to hypothesize and verify on the basis of the available evidence that proximal tubule cell (PTC) dysfunction explains well the link between the development of albuminuria/proteinuria and cardiovascular risk, especially in diabetic nephropathy which is a leading cause of CKD and is highly associated with the development of CVD.

2. Overall Functions of PTCs

The various functions of PTCs include (1) reabsorption and intracellular processing of glomerular-filtered substances such as proteins, peptides, glucose, amino acids, uric acid, sodium, potassium, phosphate, and water via apical membrane receptors, transporters, and channels; (2) uptake of substances such as protein-bound compounds via basolateral membrane transporters followed by metabolism or secretion.
Figure 1: Normal functions of proximal tubule cells (PTCs) and structural changes around the cells in the early stages of diabetic nephropathy. Normal functions of PTCs include (1) reabsorption and intracellular processing of glomerular-filtered substances via apical membrane receptors, transporters, and channels; (2) uptake of substances via basolateral membrane transporters followed by metabolism or secretion into the urinary space; (3) synthesis of bioactive substances that are released to peritubular capillaries. These functions are impaired in diabetic nephropathy even at the early stages in which PTCs are hypertrophied with increased metabolic demands and are phenotypically altered. In addition, tubular basement membranes (TBMs) are thickened, and interstitial spaces are expanded with fibrosis, alienating PTCs from interacting with peritubular capillaries.

to the urinary space; (3) synthesis of substances that are released to the peritubular capillaries (Figure 1). Impairment of these diverse functions is likely to affect systemic hemodynamic and metabolic homeostasis and may mediate the development of CVD as discussed below.

3. Dysfunction of PTCs in Diabetic Nephropathy

In the early stages of diabetic nephropathy, PTCs are hypertrophied because of increased metabolic demands and phenotypically changed to express cytokines or chemokines [4]. Tubular basement membranes are thickened and interstitial spaces are expanded with fibrosis, isolating the PTCs from interaction with peritubular capillaries (Figure 1). Such structural changes and increased metabolic demands on PTCs are likely to cause ischemia in the cells. At more advanced stages, interstitial fibrosis is increased, peritubular capillaries become dispersed, and PTCs undergo atrophy, which further diminishes interaction between the cells and surrounding capillaries. Similar phenotypic changes of PTCs are also observed in patients with obesity or metabolic syndrome. In other glomerular diseases, tubulointerstitial damage also follows as a final common pathway for progression to ESRD [5].

4. Megalin and Cubilin: Two Endocytic Receptors in Apical PTC Membranes

Glomerular-filtered substances are reabsorbed by megalin and cubilin, two endocytic receptors expressed in apical PTC membranes (Figure 2). Megalin is a large (~600 kDa) glycoprotein member of the low-density lipoprotein receptor family [6, 7] that is primarily expressed in clathrin-coated pits [8]. Megalin-ligand complexes are internalized by invagination of clathrin-coated pits mediated by multiple adaptor proteins and motor molecules, forming endosomal vesicles. Acidification of the intravesicular lumen dissociates the ligands from megalin, and they are transported to lysosomes for degradation or storage, or secreted into the cytosol for further processing or transport. Megalin is recycled to the apical membranes through a recycling compartment. Megalin thus plays a critical role in reabsorption and metabolism of glomerular-filtered substances including albumin and low molecular weight proteins. Megalin knockout mice display low molecular weight proteinuria and albuminuria [9]. Furthermore, patients with Donnai-Barrow and facio-oculo-acoustico-renal syndromes, caused by mutations in the megalin gene, show increased urinary excretion of albumin and low molecular weight proteins [10].

Cubilin is a 460 kDa peripheral glycoprotein that lacks transmembrane and intracellular segments but is anchored to apical membranes in PTCs. It was originally identified as the receptor for intrinsic factor-vitamin B₁₂ complex [11, 12]. Cubilin gene defects are the cause of hereditary megaloblastic anaemia 1 or Imerslund-Gräsbeck syndrome, known as selective vitamin B₁₂ malabsorption with proteinuria [13]. Cubilin is also involved in the absorption of various protein ligands present in glomerular filtrates, including albumin, transferrin, and vitamin D-binding protein (DBP) [8]. Cubilin requires interaction with megalin to regulate its endocytic functions [14, 15]; however, it is bound more firmly by a protein called amnionless, forming a complex named CUBAM [16, 17] (Figure 2). Amnionless, a 38–50 kDa membrane protein with a single-transmembrane domain, was initially identified as a component required for normal development of the trunk mesoderm derived from the middle streak [18]. In addition, defects of the amnionless gene cause hereditary megaloblastic anaemia [19].

5. Impaired Reabsorption of Glomerular-Filtered Substances via Megalin and Cubilin in Diabetic Nephropathy

Decreased megalin expression in PTCs has been found in the early diabetic stages of experimental animals [20, 21].
It has also been suggested that the functions of megalin are impaired in patients during the early stages of diabetic nephropathy, since low molecular weight proteinuria is frequently observed in patients at these stages [22, 23]. Therefore, the altered regulation of megalin expression and its functions must be responsible for the early development of proteinuria/albuminuria in diabetic patients. The functions of cubilin, a direct receptor for albumin, may also be impaired in the early stages of diabetic nephropathy as urinary excretion of transferrin, another endocytic ligand of cubilin, is significantly increased in patients at the early stages [24]. The functions of both megalin and cubilin are likely to be further affected as tubulointerstitial injury in CKD progresses.

Cellular expression of megalin was found to be downregulated by TGF-β [21]. We also found that megalin expression in cultured PTCs is upregulated following treatment with insulin or high-concentration glucose. Conversely, it is downregulated by angiotensin II [25]. Furthermore, we demonstrated that there is competitive crosstalk between angiotensin II type 1 receptor- and insulin-mediated signaling pathways in the regulation of megalin expression in the cells [25]. Angiotensin II may be a major factor in suppressing megalin expression in the early stages of diabetic nephropathy since intrarenal RAS is activated in the disease [26].

Decreased expression or functioning of megalin and/or cubilin results in reduced reabsorption of their glomerular-filtered ligands. Impaired reabsorption of some ligands of these receptors may be associated with the development of CVD, as described next.

6. Megalin- or Cubilin-Mediated Endocytic Ligands That May Promote Development of CVD When Depleted

6.1. Vitamin D. Megalin and cubilin take up the 25(OH)D₃/DBP complex from glomerular filtrates [27, 28] (Figure 2). In PTCs, 25(OH)D₃ is dissociated from DBP and converted by 1α-hydroxylase to 1,25(OH)₂D₃, a biologically active form, which is released to the peritubular capillaries. Therefore, dysfunction of these endocytic receptors is an important cause of deficiency of both 25(OH)D₃ and 1,25(OH)₂D₃ in CKD in addition to other factors such as decreased 1α-hydroxylase activity. Vitamin D deficiency develops very early in the course of CKD, especially in diabetic nephropathy, and is associated with the development of CVD or mortality in patients at predialysis stages [29, 30]. Treatment with the activated vitamin D analogue calcitriol was significantly associated with improved survival of patients with CKD [31, 32]. In addition, vitamin D deficiency may also be associated with an increased risk of CVD in the general population [33], although the effects of vitamin D supplementation on the CVD-related mortality in the population remain controversial.

Many studies have investigated vitamin D deficiency-associated mechanisms of vascular calcification and cardiac dysfunction. Vitamin D acts on vascular smooth muscle cells
to inhibit activators of vascular calcification, such as core binding factor-1 (Cbfa1), bone morphogenic protein-2, type I collagen, interleukin-1b, interleukin-6, and transforming growth factor-β, and to stimulate inhibitors of vascular calcification, such as matrix Gla protein and osteopontin [30]. Furthermore, decreased vitamin D-receptor activity increases circulating renin levels and blood pressure which results in left ventricular and myocyte hypertrophy [34].

6.2. Vitamin B₁₂ and Folate. Vitamin B₁₂ is a cofactor involved in the formation of methionine (Met) from homocysteine (Hcy) by cytoplasmic methionine synthase using 5-methyl-tetrahydrofolate (5-MTHF), the dominant folate form in serum, as a one-carbon donor [35] (Figure 3). Therefore, vitamin B₁₂ and/or folate deficiency results in the accumulation of Hcy that is associated with the development of CVD. Following absorption from the intestine with intrinsic factor, vitamin B₁₂ is bound in the serum with transcobalamin, a 45 kDa serum protein, for transport to target tissues. The transcobalamin-vitamin B₁₂ complex is filtered by glomeruli and reabsorbed by megalin in PTCs [36] (Figure 2), which explains why vitamin B₁₂ deficiency can be induced by decreased megalin function.

Folate binds to a carrier protein termed folate-binding protein and also to other proteins including albumin. Alternatively, it exists in free form in serum. After being filtered by glomeruli, protein-bound folate is reabsorbed by PTCs through megalin-mediated endocytosis while the free form is likely taken up by folate receptors [37] (Figure 2). Dysfunction of PTCs therefore results in decreased renal retrieval of folate, which subsequently leads to its deficiency.

6.3. Selenoprotein P. Megalin is also involved in the reabsorption of selenoprotein P, a selenium-carrier protein from glomerular filtrates [38, 39] (Figure 2). Selenium is released from selenoprotein P and used in PTCs to synthesize glutathione peroxidase 3 (GPx3), a major plasma antioxidant enzyme [40]. GPx3 is involved in maintaining the vascular bioavailability of nitric oxide, a major vasorelaxant, as well as inhibiting platelet function [41]. Therefore, reduced uptake of selenoprotein P in PTCs due to impaired megalin function may result in decreased GPx3 synthesis which may be associated with the development of vascular diseases. Notably, a recent proteome analysis revealed that serum GPx3 levels are significantly decreased in patients at the microalbuminuric stage of type 2 diabetes and even further at the progressive stages [42]. In fact, familial GPx3 deficiency has been associated with an increased risk of childhood stroke [43, 44]. Also, there have been reports that demonstrate decreased GPx3 activity among patients with coronary artery disease, supporting a broader effect of this defect in the vascular system [45–47].

7. Increased Phosphate Reabsorption in PTCs

Hyperphosphatemia is significantly associated with the development of CVD and high mortality in patients with CKD, independent of estimated creatinine clearance [48].
Inorganic phosphate appears to act directly on cultured vascular smooth muscle cells to express the osteogenic markers Cbfa1 and osteocalcin, with subsequent mineralization of the extracellular matrix [49]. Serum phosphate concentration is regulated by intestinal absorption from dietary phosphate intake, but more importantly, by glomerular filtration and reabsorption of phosphate via type II Na/Pi cotransporters (NaPi-IIa and NaPi-IIc) in the apical membranes of PTCs. In particular, NaPi-IIa plays a central role in phosphate reabsorption in the kidney (Figure 2). The presence of hyperphosphatemic patients with CKD whose GFR is normal is well explained by a hypothesis that Na/Pi cotransporters in PTCs may be inappropriately upregulated. The functions of NaPi-IIa are regulated by various hormones and hormone-like substances, such as parathyroid hormone, fibroblast growth factor 23, and Klotho that all downregulate NaPi-IIa and induce phosphaturia. Regulation of NaPi-IIa is almost exclusively mediated via receptor-mediated endocytosis and lysosomal degradation of NaPi-IIa [50]. Because megalin mediates the endocytic pathway for degradation of NaPi-IIa [51], decreased megalin function may result in hypophosphaturia or hyperphosphatemia even in cases with normal GFR.

8. Increased Sodium Reabsorption in PTCs

Proximal tubular uptake of sodium is increased in patients with diabetic nephropathy [52–54] and metabolic syndrome [55, 56] and is associated with the development of hypertension, another potent factor for CVD [57]. Na+/H+ exchanger isoform 3 (NHE3) is the main NHE isoform in PTCs and mediates isotonic reabsorption of approximately two-thirds of filtered NaCl and water, reabsorption of bicarbonate, and secretion of ammonium ions [58] (Figure 2). Enhanced NHE3 activity is assumed to play a leading role in increased sodium reabsorption in diabetes while intrarenal RAAS activation is also thought to be involved in the process [26]. Increased action of sodium glucose cotransporter SGLT2 is yet another factor promoting increased sodium uptake in PTCs in diabetes [59].

9. Impaired Metabolism of Vasculotoxic Substances Taken up via Apical Transporters/Receptors in PTCs

9.1. Homocysteine (Hcy). Hcy is a sulfhydryl amino acid formed by demethylation of Met (Figure 3). S-adenosylmethionine (AdoMet) is the intermediate in this reaction and serves as the methyl donor to form S-adenosylhomocysteine (AdoHcy). Hcy is either remethylated to Met or transsulfurated to cysteine. Approximately 75% of total plasma Hcy is bound to protein, primarily albumin, via a disulfide bond (bound Hcy), while the remaining 25% exists in a free-form unbound state (free Hcy) in humans.

When patients with extreme hyperhomocysteinemia due to genetic enzyme defects were found to suffer from premature atherosclerosis and venous thrombosis, Hcy was hypothesized to be a direct vasculotoxic agent [60]. Subsequently, it was shown that plasma Hcy is strongly associated with renal function, and that 85%–100% of ESRD patients have elevated Hcy levels [61]. Hyperhomocysteinemia is recognized as a risk marker for CVD in patients with ESRD unless their conditions are complicated with malnutrition or inflammation that induces hypoalbuminemia and apparent low plasma Hct levels [62, 63].

The kidney probably plays an important role in Hcy clearance and metabolism. It is highly likely that free Hcy is filtered by glomeruli and taken up via cationic amino acid transporters in the apical membranes of PTCs [64, 65] (Figure 2). However, renal uptake of Hcy derived from bound Hcy may be mediated by basolateral tubular transporters. It is therefore assumed that impaired uptake and/or metabolism of Hcy in PTCs are associated with hyperhomocysteinemia in patients with CKD or ESRD and the development of CVD.

Hyperhomocysteinemia is also associated with an increase in AdoHcy, which is considered another predictor of cardiovascular events. AdoHcy is a powerful competitive inhibitor of protein as well as DNA methyltransferases. Increased intracellular AdoHcy can be expected to result in hypomethylation of proteins and genes, which will in turn induce protein dysfunction and epigenetic dysregulation, respectively [66, 67].

9.2. Asymmetric Dimethylarginine (ADMA). ADMA, a naturally occurring L-arginine analogue, is an endogenous competitive inhibitor of nitric oxide synthase and an important inducer of endothelial dysfunction. ADMA is formed by the methylation of arginine residues in peptides with protein methyltransferase (PRMT) and their release after proteolysis. In this reaction, AdoMet is the methyl donor, and AdoHcy is the demethylated product. Formations of ADMA and Hcy are therefore biochemically linked (Figure 3).

An increased plasma concentration of ADMA is associated with the development of CVD [68]. In patients with nondiabetic CKD, blood concentrations of ADMA are markedly increased at an early stage, even when GFR is still within the normal range [69]. Increased plasma ADMA levels are also closely associated with the development and progression of nephropathy in patients with type 2 diabetes [70].

The kidney is an important organ for clearance of ADMA [71, 72], which is eliminated from circulation by both renal excretion and metabolic degradation. Renal uptake of ADMA is very likely mediated by cationic amino acid transporters that are predominantly expressed in the apical membranes of PTCs [73]. ADMA metabolism is mediated by dimethylarginine dimethylaminohydrolases (DDAHs), which are posttranscriptionally downregulated by reactive oxygen species and Hcy [74, 75]. Two isoforms of DDAH exist and are differentially localized and regulated. In the kidney, DDAH I is abundantly expressed in PTCs, while DDAH II is located in glomeruli, afferent arterioles, macula densa, and distal nephrons [76]. Recent studies have indicated that DDAH I is mainly involved in the regulation of plasma ADMA levels [77]. In addition, ADMA is formed by the activity of PRMT that is highly expressed in PTCs. In subtotally nephrectomized rats showing increased plasma ADMA...
levels, DDAH protein levels were decreased while expression of PRMT was increased in the kidney [78]. Such effects are likely to mediate the mechanism of increasing plasma ADMA levels. Streptozotocin-induced rat diabetic kidneys also showed decreased DDAH I expression, which was reversed by telmisartan, an angiotensin II-receptor blocker [76].

9.3. Advanced Glycation End Products (AGEs) and Free Adduct Glycation, Oxidation, and Nitration Products. Megalin mediates proximal tubular uptake of AGEs, a potent factor of vascular injury [79]. It remains unclear how effectively AGEs are metabolized in PTCs, but this metabolic process may be affected in damaged PTCs. AGE precursors which include glycation, oxidation, and nitration free adducts are also excreted or metabolized in the kidney [80]. Methylglyoxal, one such dicarbonyl adduct, is a potent glycating agent associated with oxidative stress and vascular injury [81] and is increased in the serum of patients with CKD or uremia, probably because of reduced renal metabolism [80]. Methylglyoxal is metabolized by glyoxalase I that is usually expressed in PTCs but is downregulated in the rat model of renal injury [82]. This suggests that decreased enzymatic activities in PTCs may be a cause of increased serum methylglyoxal in CKD.

10. Impaired Uptake, Metabolism, or Urinary Excretion of Vasculotoxic Substances via Basolateral PTC Transporters in PTCs

10.1. Indoxyl Sulfate and Other Protein-Bound Uremic Toxins. Indoxyl sulfate is a protein-bound uremic toxin that results from the metabolism of dietary tryptophan. Increase of serum indoxyl sulfate in patients with CKD is associated with both the development of CVD and mortality [83]. Indoxyl sulfate is excreted in urine via the organic anion transporters OAT1 and OAT3 that are predominantly expressed in the basolateral membranes of PTCs [84]. These transporters are important as they are also involved in urinary excretion of other protein-bound uremic toxins such as 3-carboxy-4-methyl-5-propyl-2-furanpropionate, indoleacetate, and hippurate, which may also be associated with the development of CVD in patients with CKD [85].

10.2. Guanidino Succinate, Transaconitate, and ADMA. SLCO4C1 is a human kidney-specific organic anion transporting polypeptide that was first identified as a digoxin transporter [86]. In renal failure, basolateral SLCO4C1 expression in PTCs is decreased; however, the expression level of multidrug resistance protein 1 that mediates the tubular secretion of digoxin in the apical membranes of PTCs is not changed [86]. A kidney-specific transgenic rat line overexpressing human SLCO4C1 in PTCs was shown to significantly eliminate the uremic toxins guanidino succinate and trans-acconitate as well as ADMA from circulation, even when renal failure was induced by 5/6 nephrectomy [87]. In this study, pravastatin was also found to upregulate the expression of SLCO4C1 and facilitate the removal of circulating ADMA.

11. Decreased Synthesis of Vasculoprotective Substances by PTCs

As mentioned earlier, vasculoprotective substances such as 1,25(OH)2D3 and GPx3 are synthesized by PTCs and secreted into circulation. In addition, renalase, a circulating monoamine oxidase, is a similar substance that is synthesized by the PTCs and regulates various cardiac functions and blood pressure [88]. Plasma concentrations of these factors are reduced in patients with CKD most likely because of decreased synthesis in the PTCs.

12. Therapeutic Strategies for Targeting PTC Dysfunction

Given the diverse and complex functions of PTCs, it is important to establish comprehensive therapeutic strategies to preserve PTC viability and maintain their broad range of functions in diabetic nephropathy and other disorders related to CKD. Therefore, it may not be sufficient to compensate only for specific functions of the cells; in fact, such an approach may explain why the outcomes of recent supplemental trials that used vitamin B12 and folate to target Hcy levels were controversial [89, 90]. In addition, vitamin B12 and folate deficiencies due to decreased PTC uptake may be masked by reduced GFR in advanced stages of CKD. Therefore, supplementation with these vitamins could lead to overdose and adverse side effects. Inhibitors of the renin-angiotensin II system and statins may effectively alleviate PTC dysfunction; however, the mechanisms of these agents acting on PTCs remain to be elucidated as the phenotypes or pharmacological responsiveness of PTCs may change according to pathogenic stages. Therefore, it is also necessary to develop effective biomarkers to evaluate and monitor the stages of PTC dysfunction.

13. Conclusions

Dysregulation of PTC functions is likely to mediate the multifactorial mechanisms of the development of CVD as well as progression to ESRD and therefore plays a role in cardiorenal syndrome. In particular, PTC dysfunction occurs at the early stages of diabetic nephropathy, a leading cause of CKD. It is important to elucidate the mechanisms of PTC dysfunction and establish therapeutic strategies that protect against PTC dysregulation.
