ABSTRACT. In the last decade the sol-gel process became a promising method to synthesize materials in form of coatings, nanoscale powders and porous systems. Several products or devices made with such a process already exist on the market. This paper briefly reviews the state of the art in the development of electrochromic coatings and devices and nanocrystalline solar cells achieved during the last decade using *sol-gel* derived pure and doped *niobium pentoxide*.

1. INTRODUCTION

Stoichiometric niobium oxides mainly exist in the form of NbO, Nb₂O₃, NbO₂ and α , β Nb₂O₅ [1]. Niobium pentoxide is however the most studied material. It has been prepared by different methods such as oxidation of metallic niobium in air, by hydrolyzing alkali-metal niobates, niobium alkoxides and niobium pentachloride or by precipitation from solution in hydrofluoric acid with alkali-metal hydroxide or ammonia [2]. Nb₂O₅ possesses a quite complex crystalline morphology. The phases most often found have been labeled T, TT, B, M and H [3, 4] and their appearance depends on the preparation method of the compound and the kinetics and thermodynamics. The T and TT phases are essentially observed below 800 °C and the TT phase, indexed as pseudohexagonal, is thought to be a modification of the orthorhombic T phase as it presents a lower crystallinity and is probably stabilized by impurities such as OH⁻, Cl⁻ or vacancies [5]. Stoichiometric Nb₂O₅ is an insulator [1], but it becomes a *n*-type semiconductor at lower oxygen content.

Traditionally niobium pentoxide is used in metallurgy for the production of hard materials or in optics as additive to prevent the devitrification and to control the refractive index of special glasses. In electronics it is used for the preparation of electroacoustic or electrooptical components such as LiNbO₃ and KNbO₃ or relaxor ferroelectric ceramics such as Pb(Mg_{1/3}Nb_{2/3})O₃ [2]. However, in the last 15 years, its interesting semiconducting properties and the advent of more sophisticated methods of preparation allowed the obtaining in a controlled way of innovative systems such as highly porous materials, very fine powders and coatings. These new materials have found further

important application in the field of electrochromism, batteries, solar cells and catalysis [6].

This paper summarizes the recent results obtained in the field of electrochromism (Section 2) and nanocrystalline solar cells, the so-called Graetzel cells (Section 3) with pure and doped *niobium pentoxide* prepared by the *sol-gel* process, although some references are also given for comparison for other preparation routes. A conclusion follows in Section 4.

2. Nb₂O₅ ELECTROCHROMIC (EC) COATINGS AND DEVICES

General reviews on the preparation and on the properties of electrochromic coatings and devices prepared by the *sol-gel* method have been already published by Agrawal *et al.* [7] and the author [8–10].

The first mention of a persistent but reversible optical change produced electrochemically in Nb₂O₅ coatings was published by Reichman and Bard in 1980 [11]. Such an effect was observed on a niobium metallic disk oxidized at approximately 500 °C for 10 min. The blue coloring effect, seen in reflection under H⁺ and later also under Li⁺ insertion [12], was chemically stable and showed fast kinetics (1 to 2 s).

Since then several more adequate deposition techniques have been used to obtain niobium oxide EC films among which CVD [13], DC magnetron sputtering [14], electrochemical method [15] and the dip or spin coating process via the *sol-gel* route [6].

2.1. Pure niobium oxide sol-gel coatings and devices. Lee and Crayston [16] were the first to show that pure sol-gel Nb₂O₅ coatings present an electrochromic effect. They prepared 5 to 10 μ m thick coatings by spinning a hydrolyzed solution of NbCl₅ dissolved in ethanol on ITO coated glass. The films showed

[†]E-mail: aegerter@inm-gmbh.de

[‡]E-mail: michael.schmitt@din.de

a blue coloration with fast coloration (approx. 6 s) and bleaching (approx. 3 s) kinetics and a coloration efficiency of $6 \text{ cm}^2/\text{C}$ but the durability of the EC response was only a few cycles.

Since then many sol compositions and preparation routes have been tested and an analysis of the published reports [6] shows that the best niobium oxide coatings for EC purpose prepared by the *sol-gel* process are those made from alkoxides or chloroalkoxides based sols. The choice of the precursor does not seem to have a large influence on the final EC properties. However, according to Schmitt *et al.* [17, 18], the amount of lithium ions which can be inserted reversibly into the films as well as the corresponding change of the optical density both decrease with increasing length of the alkyl chain. Therefore ethanol is the preferred solvent for the sol preparation. Large indium tin oxide (ITO) or fluorine doped tin oxide (FTO) coated glass substrates can thus be coated by the dip coating process at a withdrawal rate of typically 2 mm/s . Depending on the sol concentration the thickness of the resulting films varies between 30 and 140 nm and the coating procedure has to be repeated several times to obtain thick coatings, each layer being previously dried and partly sintered at 400°C before the next deposition step. Thick coating stacks can be sintered up to 600°C , which is the highest temperature allowed to keep the commercial conductive substrates with good electrical properties.

The results presenting here have been obtained with coatings deposited by the dip-coating process using sols obtained by the chloroalkoxide route i.e. by dissolving NbCl_5 in ethanol and acetic acid [17, 18]. Figure 1 shows a typical differential thermal analysis (DTA) and thermogravimetry (TG) of a pure Nb_2O_5 xerogel dried at 100°C . An endothermic peak is first observed at about 200°C followed by an exothermic peak at 250°C . Both peaks are accompanied by a 9% mass loss due essentially to the evolution of the solvent molecules (fraction

Figure 1. DTA and TG curves measured at 10 K/min of a Nb_2O_5 xerogel dried at 100°C prepared by the chloroalkoxide route [17, 18].

of the type C_xH_y (mass 26, 27, 39, 42, 43, 55, 66, 57) and to a minor extent, the evolution of HCl (mass 36 and 37) as obtained by a simultaneous mass spectrometry (MS) analysis [17, 18]. These results are indicative of the building up of an inorganic amorphous network, as confirmed by the X-ray diffractograms (Figure 2).

Figure 2. X-ray diffraction of a two layers undoped Nb_2O_5 coatings (thickness approx. 120 nm) deposited on ITO coated glass sintered between 400 and 600°C . (o: ITO-peaks. Vertical lines JCPDS 28-317 data (hexagonal structure of Nb_2O_5)) [17, 18].

The second large exothermic double peak at about 470°C is accompanied by a smaller mass loss of 2.5%. MS analysis indicates that the loss corresponds essentially to the evolution of HCl (mass 36 and 37) and to the same fractions of organic molecules as above. The DTA peaks correspond to a crystallization process (Figure 2). A detailed analysis indicates that in the temperature range 460 to 600°C the niobium oxide films exhibit the hexagonal structure (TT phase) with crystallite size of about 70 nm. The layers were found to be highly (001) oriented.

The results of electrochemical-optical studies can be classified in three groups depending on the sintering temperature. Typical cyclic voltammetry curves measured at a 50 mV/s rate between $+1 \text{ V}$ and -2.2 V vs. Ag/AgClO_4 during the 50th cycle are given in Figure 3 for amorphous coatings sintered at 450°C and for crystalline samples sintered at 500°C (low crystallinity) and 600°C (high crystallinity). All coatings are approx. 120 nm thick with a 6.6 cm^2 area. The measurements have been done using a 3-electrode optical cell containing a 1 M-solution of LiClO_4 dissolved in propylene carbonate as electrolyte and a Ag/AgClO_4 (0.01 M-solution dissolved in the used electrolyte) as reference electrode. For all materials, the reduction of Nb^{V} to Nb^{IV} occurs below -1 V and the peak maximum which lies below -2.2 V is not observed. The maximum of the oxidation peak lies at about -1.2 V for

Figure 3. 50th cycle voltammetry curves of two layers Nb₂O₅ coatings (thickness approx. 120 nm) sintered at 450 °C (amorphous) and 500 and 600 °C (crystalline) [17, 18].

the amorphous phase and is shifted to more negative potentials as the crystallinity increases. The width of the oxidation peak is larger for amorphous coatings indicating slower bleaching kinetics than for crystalline samples. For the crystalline samples the height of the peak increases and shifts to higher potentials with increasing temperature.

Figure 4 shows chronoamperometric curves measured during the 50th cycle for the same samples with voltage of -2.2 V and +1 V applied during 120 s. Coloration kinetics is always found slower than the bleaching one. For the crystalline samples the kinetics of both coloration and bleaching becomes faster as the sintering temperature increases and reaches practically the same value at 600 °C as those of the amorphous phase at 450 °C. The diffusion coefficients D for Li as determined by analyzing the time behavior $I(t) \sim D^{0.5}t^{-0.5}$ [19] are in the range of 10^{-11} cm²/s and slightly increase with the sintering temperature.

Figure 4. 50th chronoamperometric cycle (-2.2 V; +1.0 V vs. Ag/AgClO₄) of two layers Nb₂O₅ coatings (thickness approx. 120 nm) sintered at 450 °C (amorphous) and 500 and 600 °C (crystalline) [17, 18].

Figure 5 shows the spectral dependence of the change of the optical density ($\Delta OD = -\log_{10}(T_{\text{bleached}}/T_{\text{colored}})$) of the same samples measured during the 50th chronoamperometric cycle. The spectra are quite different and reflect the fact that the coatings, when seen in transmission, color brown in the amorphous state ($T < 450$ °C) and blue in the crystalline state (TT phase for $T > 500$ °C). For both types of morphology ΔOD increases with the sintering temperature reflecting faster kinetics as discussed above (Figure 4).

Figure 5. Spectrum of the optical density change ΔOD of two layers Nb₂O₅ coatings (thickness approx. 120 nm) sintered at 450 °C (amorphous) and 500 and 600 °C (crystalline) measured during the 50th chronoamperometric cycle (-2.2 V, 120 s; +1.0 V, 120 s vs. Ag/AgClO₄) [17, 18].

To make practical devices, it is mandatory to know the electrochemical and optical behavior as a function of the number of applied electrochemical cycles. The optical change and amount of Li⁺ charge inserted and extracted have been measured up to 5000 chronoamperometry or voltammetry cycles under the above specifications and found stable with a coloration efficiency of 18.8 cm²/C at 550 nm (amorphous coatings) and that the coloration kinetics become slower and the bleaching one faster as the number of cycles increases. Similar responses were also found with the crystalline coatings sintered between 500 °C and 600 °C. The layers are also stable up to at least 5000 cycles but the coloration efficiency at 550 nm is lower, approx. 16 cm²/C. These values are significantly smaller than the 35 cm²/C obtained for films made with Nb ethoxide but measured under H⁺ insertion at 700 nm [20] and for sol-gel WO₃ layers, the best EC coatings at present, which possess a coloration efficiency of about 50 cm²/C after sintering at 220 °C [21]. It is also worth to mention the value of 35 cm²/C obtained by Yoshimura *et al.* for Li⁺ insertion into a niobia film made by DC magnetron sputtering [14] and the very high coloration efficiency of 160 cm²/C measured at 550 nm in the early stages of coloration by H⁺ insertion by Maruyama

et al. [13] for an amorphous niobia film made by a CVD process.

The *sol-gel* made niobium oxide is therefore an interesting candidate to realize solid state EC cells as it results in good coating, offers the possibility to get thick transparent coatings and shows reasonable coloration efficiency and high reversibility and stability under H^+ or Li^+ insertion. However, the results have been quite disappointing till today. Avellaneda [22] realized a cell with the configuration glass/ITO/ Nb_2O_5 /electrolyte/ $CeO_2 - TiO_2$ /ITO/glass. By switching between +1.5 to -2.0 V only a very small Li insertion has been observed, typically 2.5 mC/cm^2 but no coloration has been observed. Schmitt [18], using the same configuration with a 125 nm thick Nb_2O_5 and a 240 nm thick $CeO_2 - TiO_2$ counter electrode measured also a very small Li insertion ($< 0.25 \text{ mC/cm}^2$ after switching between -2.5 V and +1 V during 120 s) with a corresponding change in optical density at 500 nm lower than 0.01 ! Only Orel *et al.* [23–25] succeeded to observe a transmission change between 60% and 33% using a *sol-gel* $SnO_2 : Sb(7\%) : Mo(10\%)$ layer as counter electrode (IS) switching between -4.0 V(!) and +2.0 V during 120 s. Due to the very high negative applied potential, the cell had a very poor stability, less than 500 cycles. These poor results have been explained by Schmitt *et al.* [18, 26] using a model originally developed by Bullock and Branz [27] as being due to the too large difference existing between the internal (Fermi) potential of pure Nb_2O_5 and the ion-storage electrodes.

2.2. Doped niobium oxide sol-gel coatings and devices. Niob(V)oxide has been either used as a doping material for already known electrochromic materials or has been doped with different compounds [6].

For the last case, the most detailed development has been made recently by Schmitt *et al.* [17, 18] who mixed $NbCl_5$ /ethanol/acetic acid sols with compounds of Li, (incorporated as $LiCF_3SO_3$ or lithium acetate), Ti (as $[(CH_3)_2CHO]_4Ti$), Sn (as $SnCl_4 \cdot 5H_2O$), Zr (as $ZrOCl_2 \cdot 8H_2O$) and Mo (as $H_3Mo_{12}O_{40}P \cdot xH_2O$) to study the influence of the doping on the EC properties of *sol-gel* coatings sintered between 400 and 600 °C and devices [18, 26]. The overall behavior of the DTA/TG curves was found similar to that shown in Figure 1. However, depending on the type and amount of doping, the temperature of the formation of the inorganic amorphous network and of the crystallization processes were slightly different. Except for Mo doping all layers were found amorphous between approx. 250 °C and 450 °C and after Li^+ insertion the color in transmission were brown as for the pure niobium oxide. However, besides the already known TT and T phases leading to a blue coloring effect, other structural phases such as $LiNb_3O_8$, $Ti_2Nb_{10}O_{29}$, Nb_2O_{29} , etc. have been observed at higher sintering temperature. In

their presence the layers colored gray under Li^+ insertion. A detailed analysis of these results shows that the color of the layers is essentially dependent on the size of the crystallites and not on the crystal structure of the materials.

The three typical spectra observed in this study are shown in Figure 6. A shift of the peak maximum of the spectra as a function of the morphology was also observed for WO_3 . Amorphous layers have an absorption maximum at 900 nm while for well crystalline layers the peak lies at 1400 nm [28, 29]. However, as both peak maxima are lying in the infrared, the resulting color of both coatings remains blue. The absorption mechanism for the brown amorphous niobia layer is thought to arise from polaron absorption. As the crystalline order increases the absorption band becomes broader and the blue color can probably be explained by the Drude model in which the absorption is essentially governed by interaction with free electrons (high reflection).

Figure 6. Typical optical spectra ΔOD vs. λ) of pure and Ti doped niobia EC layers after Li^+ ions insertion. Well ordered layers with crystallite size $> 30 \text{ nm}$ show a blue color, weakly ordered layers with crystallite size $< 25 \text{ nm}$ show a gray color while all amorphous layer have a brown color [17, 18].

Layers sintered between 450 and 600 °C have been investigated up to 5000 cycles and, whatever the type and amount of doping and the sintering temperature, the EC properties have been found stable. The niobium oxide layers doped with Sn and Zr are still electrochromic but no improvement has been observed as the amount of Li^+ ions which can be inserted into the layer and consequently the change of the optical density decreased with increasing doping level. Nevertheless the coloration efficiency remains about the same at approx. $17 \text{ cm}^2/\text{C}$. As it was already observed [23], the incorporation of Li^+ improves the kinetics and the coloration efficiency increased to approx. $23 \text{ cm}^2/\text{C}$ up to a molar ratio $Li/Nb = 0.1$ for the crystalline layers sintered between 500 and 600 °C.

At 450 °C all the layers were amorphous and colored brown. At 500 °C only gray and brown colors have been found depending on the amount of doping while at 600 °C the colors were gray and blue. With Ti doping the coloration efficiency was also found to increase for crystalline layers (up to 27 cm²/C at 600 °C). Amorphous layers coloring brown were found at 450 °C and up to 500 °C for high doping (Ti/Nb > 0.3). At lower doping the layers colored blue for $T > 500$ °C. However, gray color was found for high doping at 600 °C.

The most interesting results were found for Mo doping. The pure (001) oriented hexagonal structure was already found at 450 °C for doping with 5 at% and up to 500 °C with 10 at% leading to a blue color. A pure weakly crystalline orthorhombic phase (Nb₁₂O₂₉) with small crystallites (15–20 nm) was observed in films doped with 20 and 30 at% sintered at 450 and 500 °C leading to a gray color and a mixed structure with hexagonal Nb₂O₅ and orthorhombic Nb₁₂O₂₉ crystallite was observed with a 20 at% Mo doping sintered at 450 °C and for all doped samples sintered at 600 °C. A high doping (> 15 at%) drastically favors an increase of the amount of Li⁺ ions charge which can be incorporated into the layers and consequently a higher optical density change is observed.

Only two groups have reported the use of doped niobia as an EC electrode. Orel *et al.* [24, 25] have built solid state cells with the configuration glass/FTO/Li_xNb₂O₅/ormolyte/SnO₂:Sb:Mo/FTO/glass. The molar ratio was Li/Nb = 0.1 and the niobia layer was sintered at 500 °C. Such cells have been switched between –4 V and +2 V and exhibited a gray color in the colored state and transmission change up to 45% have been observed in the early cycles. Their lifetime was however short (< 500 cycles) due to the high negative potential used to obtain a coloration which is out of the range of the stability of the EC, IS and electrolyte layers. The second successful result has been obtained by Schmitt *et al.* [18, 26] who used the configuration glass//FTO/doped niobia/electrolyte(liquid)/CeO₂ – TiO₂/FTO/glass. Applying the model developed by Bullock *et al.* [27], they show that, for this configuration, a reasonable coloration within the safe voltage range of ±2.5 V could only be obtained with Mo doped niobia. The most important parameters necessary to simulate the coloration behavior of the cell are the Fermi potentials of both layers (Figure 7) which have been determined from coulometric titration curves by applying a current density of 5 μA/cm². The Fermi potential increases significantly with the sintering temperature (shown here for pure Nb₂O₅). It remains similar for Li and Ti doped materials but decreases drastically for Mo doped niobia. Within the safe voltage range (±2.5 V) required by the used electrolyte, all EC layers can

Figure 7. Fermi potential curves determined from coulometric titration after the 50th chronoamperometric cycle for different pure and doped niobium oxides as well as for the ion storage layer TiO₂ – CeO₂ [18, 26].

incorporate a large amount of Li ions up to $x \cong 1$. The results are however quite different for the CeO₂ – TiO₂ ion storage electrode and within the safe potential range only a small amount of Li up to $x \cong 0.14$ can be intercalated.

As the coloration efficiency for doped niobia is at most about 25 cm²/C, a minimum amount of charge of approx. 40 mC is necessary to obtain a change of the optical density of about 1. According to the results discussed above this is readily realizable in an electrochemical cell with all niobia layers having a thickness of about 300 nm. In a device this charge should be switched back and forth between the EC and IS electrodes. The model simulation shows that the best EC material is Mo doped niobia and that the thickness of the CeO₂ – TiO₂ IS electrode should be typically 10 to 20 times thicker than that of the EC layer! This of course is technically not realizable. Cells made with smaller thickness will color but with a lower optical density variation. Figure 8 shows the change of light transmittance, $\Delta\tau$, calculated according to DIN EN410 (weighted with the light function D_{65} and the human eye sensibility for day-light $V(\lambda)$) versus the number of cycles of 6×8 cm² devices made with a 180 nm thick Nb₂O₅ • 0.4Mo EC electrode sintered at 600 °C and a TiO₂ – CeO₂ IS electrode made according to reference [30] with a thickness varying between 240 nm (1 layer) to approx. 950 nm (4 layers). A voltage of ±2.5 V was applied during 120 s (each cycle).

The results obtained confirm only partially the simulation results. A thicker IS layer leads effectively to an increase in the transmission change but the response does not vary linearly. This is probably due to the fact that the ionic conductivity of these layers is low (which

Figure 8. Change of light transmittance $\Delta\tau$ calculated according to DIN EN 410 (weighted with the relative light function D_{65} and the human eye sensibility for day-light $V(\lambda)$) vs. the number of cycles of $6 \times 8 \text{ cm}^2$ devices made with a 180 nm thick $\text{Nb}_2\text{O}_5 \cdot 0.4\text{Mo}$ EC electrode and a $\text{TiO}_2 - \text{CeO}_2$ IS electrode having a thickness varying between 240 nm (1 layer) to approx. 950 nm (4 layers). Applied voltage: -2.5 V ; $+2.5 \text{ V}$ each during 120 s [18, 26].

is not taken into account by the model). In the early cycles the change of transmission is low but it strongly increases with the number of cycles, then passes by a maximum and decreases. It is believed that the deterioration of the cells is due to a corrosion effect between the electrolyte and the IS electrode. The highest amount of charge exchanged was 18 mC/cm^2 obtained with 3 IS layers and the maximum change in transmission was $\Delta\tau = 0.28$. The best cells were stable up to about 20000 cycles. These results however clearly show that a better IS electrode having a flatter Fermi potential variation and allowing a much higher Li^+ ions capacity should be developed in order to use niobium oxide as an EC material for the realization of EC devices.

3. SOLAR CELLS

Since the discovery by Graetzel [31, 32] that a dye sensitization of a porous coating of crystalline TiO_2 nanoparticles could be used for the development of solar cells, many other wide-band gap semiconductors, including niobia, have been studied. Most of the cells tested till now consisted of a thick porous coating of crystalline nanoparticles, deposited on a transparent conducting glass substrate, and whose particles were coated with a chemically adsorbed monolayer of a Ru(II) -complex. The system is completed by an electrolyte with an iodide/triiodide redox mediator and a counter electrode comprising a catalyst. For TiO_2 the overall conversion efficiency measured under 1000 W/m^2 solar simulator irradiation varies typically between 7 and

12% with an open circuit photovoltage of 0.7 to 0.8 V. As the conversion efficiency strongly depends on the surface area available to sensitize the semiconducting particles, the sol-gel process is therefore particularly adequate for the preparation of such porous coatings.

Several works have been reported with niobia coatings made by the *sol-gel* process [6]. Hu *et al.* [33] prepared niobia colloidal suspensions by hydrolyzing niobium alkoxide solutions (Nb(OEt)_5 dissolved in ethanol added to a triethylamine ethanolic aqueous solution and water) and autoclaving at 250°C . The films fired at 500°C had the TT structure, were porous and presented a morphology consisting of needles. The authors only mention that a cell made with such a layer after coating with a Ru(II) -complex gave a current conversion efficiency (IPCE) of 40% and an open circuit voltage of 0.4 V, both values being much smaller than those obtained with TiO_2 . Wolf [34], using similar preparation techniques, showed that the specific BET area of the sintered materials was in the range of 30 to $50 \text{ m}^2/\text{g}$ and that the coatings had an IPCE of 33% at 550 nm . 0.45 cm^2 size cells presented an almost constant conversion efficiency of 2.5% under simulated solar light irradiation up to 100 mW/cm^2 (1 sun). The open circuit voltage, short circuit current and IPCE were found to decrease steadily by doping niobium oxide with Ta ($\text{Nb}_{1-x}\text{Ta}_x$) $_2\text{O}_5$ up to $x = 0.25$. Lenzman [35] prepared stable colloid solutions of Nb_2O_5 hydrolysis, an alkoxide solution, Nb(OEt)acac , in a solution of water, ethanol and DBV followed by an autoclaving process at 230°C during 12 h. A water based paste formulation prepared by adding hydroxypropyl cellulose allowed to realize up to $15 \mu\text{m}$ thick, translucent Nb_2O_5 coatings by a tape casting process. After firing at $T > 500^\circ\text{C}$, the coatings consisted of an agglomeration of about $20 \mu\text{m}$ poorly defined particles, several of them having also large needle shape with a BET area of $55 \text{ m}^2/\text{g}$ at 600°C . Under 1000 W/m^2 solar irradiation, a 0.5 cm^2 Ru -complex sensitized cell $15 \mu\text{m}$ thick had an efficiency of 4%, a fill factor of 69%, $V_{\text{oc}} = 595 \text{ mV}$ and $I_{\text{sc}} = 9.7 \text{ mA/cm}^2$. The current response was found linear between 10 and 100 mW/cm^2 solar light irradiation.

Sayama *et al.* [36] prepared 1 cm^2 dye sensitized cells where a 6 to $8 \mu\text{m}$ thick niobia electrode was made by spreading a slurry of either commercial powders or powders made by calcining niobium hydroxide between 300 and 900°C . The coatings were porous and appear as an agglomeration of $100\text{--}200 \text{ nm}$ size particles. However, the overall photoelectrochemical results were not good. An improvement was obtained by dropping niobium alkoxide on 700°C sintered coatings (made from Nb hydroxide) and then calcining the system again at 500°C . The surface of the particles became rougher and thus allowed to increase the amount of dye adsorbed on

the surface by a factor of 1.2 resulting in an increase of the photoconductivity between the particles. Nevertheless the overall solar-to electric conversion efficiency remained low, typically 2% under AM1.5 (1000 W/m^2) irradiation.

The results of the author's group have been obtained by spin depositing on FTO coated glass partially hydrolyzed ethanolic niobia sols submitted to an ultrasonic treatment and then boiled under reflux [37, 38]. The BET surface of any of the coatings were found to increase with the sintering temperature up to a maximum of $26 \text{ m}^2/\text{g}$ (500°C) and then to strongly decrease down to $13 \text{ m}^2/\text{g}$ at 650°C . The maximum amount of dye which could be adsorbed on a $10 \mu\text{m}$ thick layer was $3.3 \cdot 10^{-8} \text{ mol/cm}^2$. The current response of 0.2 cm^2 solar cell realized with such coatings was not linear with the solar irradiation intensity and the solar-to-electric corrosion decrease from about 4.9% ($I < 100 \text{ W/m}^2$) to 2% ($I = 1000 \text{ W/m}^2$).

A modification of the morphology of the films was obtained by adding to the sol a polymeric ligand and carbon soot [39]. The deposited nanoscopically phase-separated film allows to obtain extra micropores during the burn-out of the organic products. Although the average porosity (about 45%) and the BJH pore size diameter (9 nm) did not change, the BET surface area, the amount of dye adsorbed and the roughness factor were all effectively increased to about $45 \text{ m}^2/\text{g}$, $8.8 \cdot 10^{-8} \text{ mol/cm}^2$ and 530, ($10 \mu\text{m}$ thick layer) respectively after a sintering at 520°C .

Some results of the ICPE of the layers is shown in Figure 9 and 10. The layers were sensitized by a Ru(II)-complex and the electrolyte was a mixture of 80% propylene carbonate (PC) and 20% acetonitrile (ACN) containing I^-/I_3^- as a redox mediator. Figure 9 shows that the IPCE of a $10 \mu\text{m}$ thick layer increases with the sintering temperature up to maximum value of about 51% (600°C). For this temperature, the IPCE was also found to increase with the thickness of the layer, saturating for a value of about $16 \mu\text{m}$ (Figure 10). Moreover, Figure 11 shows that the spectral shape of IPCE obtained with a TiO_2 coating (from INAP, Gelsenkirchen) and Nb_2O_5 measured under the same conditions are practically identical.

Nb_2O_5 solar cells with an area of 4 cm^2 have been realized. Figure 12 shows their configuration. Their electrical characterization has been measured by irradiating a spot of 1 cm^2 from a AM 1.5G solar light simulator (Oriel, SP81160-1452) whose intensity was varied up to 1000 W/m^2 . Figure 13 shows typical I-V curves obtained for different solar light irradiation. A summary of the data as well as a comparison of the electric characterization with Nb_2O_5 -solar cells made in other laboratories (EPFL [34, 35] and NIM [36]) and of a 0.4 cm^2 TiO_2 cell [40] is shown in the Figure 14.

All the Nb_2O_5 and TiO_2 cells exhibit a linear behavior of the short circuit current with the light

Figure 9. Variation of the IPCE of a Nb_2O_5 -PEG (MW = 20000) + C soot layer with the sintering temperature. The thickness of the layers is about $10 \mu\text{m}$.

intensity (Figure 14(b)). Under 1 sun irradiation, our cell has a value of 12.2 mA/cm^2 , higher than those made

Figure 12. Configuration of a 4 cm² area Nb₂O₅ solar cell.

at EPFL and NIM. The open circuit potential slightly increases with the light intensity from about 0.60 to 0.665 V and is also slightly higher than the other one (Figure 14(c)). However as can be seen from the shape of the I-V curves, a strong decrease of the fill factor from about 0.72 down to 0.48 is observed in our cell and the value under 1 sun is smaller than those reported at EPFL and NIM (Figure 14(d)). This strong decrease drastically affects the solar-to-electric conversion (Figure 14(a)) which decreases from about 7% (100 W/m²) down to 4.0% under 1000 W/m², a value also achieved

at EPFL [35]. The overall values of η are also lower than those obtained with cells made with sensitized TiO₂ nanocrystalline cells [40].

The results so far obtained by us for Nb₂O₅-solar cells are nevertheless quite promising. At low solar irradiation, the efficiency of a large 4 cm² Nb₂O₅ cell is already 70% of that obtained with a 0.4 cm² TiO₂ cell [40]. It is believed that improvement can be obtained by designing a better configuration in particular by reducing the size of the cell and also the thickness of the electrolyte.

Figure 14. Comparison of the electrical characterization of Nb₂O₅ solar cells made in different laboratories (INM (■), EPFL ▲ [34], ▼ [35], and NIM ♦ [36] and TiO₂ ● [40]). Note that the configuration, areas, electrolyte and dye are different for each cell (a) solar-to-electrical conversion η (%) (b) short circuit current I_{sc} (mA/cm²) (c) open circuit voltage V_{oc} (V) (d) fill factor FF .

4. CONCLUSION

This paper has briefly summarized the state of the art achieved with pure or doped niobium pentoxide made by sol-gel processes in the field of electrochromism and nanocrystalline solar cells. Since its first preparation in 1986, many laboratory developments have been done for the use of this material either in the form of thin or thick coatings, powders, xerogels or aerogels. Pure and doped niobium oxide coatings exhibit quite good and stable properties for the intercalation of H⁺ and Li⁺ ions and are promising compounds for the development of electrochromic devices. 100 to 300 nm thick layers can be used reversibly either as EC or IS electrodes with a lifetime higher than 10⁴ cycles. Depending of the type of doping and the sintering temperature

the color of the layers seen in transmission may be brown, gray or blue. Their use in such devices is however dependent on the discovery of an adequate counter electrode. As niobium oxide has quite similar semiconducting properties as TiO₂ its use in the form of thick porous coatings for the development of nanocrystalline solar cells has also been demonstrated. The 7% solar-to-electric conversion obtained at low light intensity illumination (< 100 W/m²) is already 70% of that obtained with titania. Such coatings are therefore quite promising but a development is still needed to increase the efficiency at all illumination level.

ACKNOWLEDGEMENT

The authors thank the Federal Ministry for Education,

Research and Technology of Germany and the State of Saarland (Germany) for their financial support.
