This paper deals with a series of new unsymmetrically substituted mesoporphyrins: 5-(2-hydroxyphenyl)-10,15,20-tris-phenyl-21,23-H-porphyrin (TPPOH_O), 5-(3-hydroxyphenyl)-10,15,20-tris-phenyl-21,23-H-porphyrin (TPPOH_M), 5-(4-hydroxyphenyl)-10,15,20-tris-phenyl-21,23-H-porphyrin (TPPOH_P), 5-(2-hydroxyphenyl)-10,15,20-tris-butyl-21,23-H-porphyrin (TBPOH_O), and their parent nonsubstituted compounds, respectively, 5,10,15,20-tetrakis-phenyl-21,23-H-porphyrin (TPP) and 5,10,15,20-tetrakis-butyl-21,23-H-porphyrin (TBP). Several photophysical studies were carried out to access the influence of the unsymmetrical substitution at the porphyrinic macrocycle on porphyrin's photophysical properties, especially porphyrin's efficiency as singlet oxygen sensitizers. The quantum yields of singlet oxygen generation were determined in benzene ($\Phi_{\Delta}(\text{TPP}) = 0.66 \pm 0.05$; $\Phi_{\Delta}(\text{TPPOH}_O) = 0.69 \pm 0.04$; $\Phi_{\Delta}(\text{TPPOH}_M) = 0.62 \pm 0.04$; $\Phi_{\Delta}(\text{TPPOH}_P) = 0.73 \pm 0.03$; $\Phi_{\Delta}(\text{TBP}) = 0.76 \pm 0.03$; $\Phi_{\Delta}(\text{TBPOH}_O) = 0.73 \pm 0.02$) using the 5,10,15,20-tetraphenyl-21,23-H-porphine ($\Phi_{\Delta}(\text{TPP}) = 0.66$) and Phenazine ($\Phi_{\Delta}(\text{Phz}) = 0.83$) as reference compounds. Their fluorescence quantum yields were found to be ($\Phi_f(\text{TPPOH}_O) = 0.10 \pm 0.04$; $\Phi_f(\text{TPPOH}_M) = 0.09 \pm 0.03$; $\Phi_f(\text{TPPOH}_P) = 0.13 \pm 0.02$; $\Phi_f(\text{TBP}) = 0.08 \pm 0.03$ and $\Phi_f(\text{TBPOH}_O) = 0.08 \pm 0.02$ using 5,10,15,20-tetraphenyl-21,23-H-porphine as reference $\Phi_f(\text{TPP}) = 0.13$). Singlet state lifetimes were also determined in the same solvent. All the porphyrins presented very similar fluorescence lifetimes (mean values of τ_S (with O₂, air equilibrated) = 9.6 ± 0.3 nanoseconds and (without O₂, argon purged) = 10.1 ± 0.6 nanoseconds, resp.). The phosphorescence emission was found to be negligible for this series of unsymmetrically substituted mesoporphyrins, but an E-type, thermally activated, delayed fluorescence process was proved to occur at room temperature.

1. Introduction

The role that porphyrins like hemoglobin or chlorophyll play in important processes as respiration or photosynthesis is well known and is now well understood [1, 2]. In spite of the importance of porphyrins in the treatment of psoriasis, atheromatous plaque, and several viral and bacterial infections including AIDS [3–6], nowadays their use for cancer photodynamic therapy (PDT) has become

undoubtedly porphyrin's most relevant application [7–15]. Although some promising studies with other classes of compounds were already reported in literature [16–19], until now, very few PDT drugs were approved for human use and all of them are still porphyrins [20, 21].

The usefulness of porphyrins in cancer therapy originates from their ability for the generation of singlet oxygen [22–25], a very reactive species considered to be the cytotoxic agent in the photodegradation of malignant cells [7–25].

Once administrated to the patient, the photosensitizing PDT drugs are preferentially concentrated in malignant cells. After photosensitizer's selective concentration in cancer tissue, the tissue is irradiated with light suitable for the excitation of the sensitizer. If oxygen is nearby ($^3\text{O}_2$), an energy transfer process takes place, the sensitizer returns to its ground state, and an excited singlet state oxygen molecule ($^1\text{O}_2^*$) is generated. Singlet oxygen is a very aggressive species that quickly reacts and destroys cancer cells which are closely located [7–25].

In addition to the need for the photosensitizers to have a strong absorption in the phototherapeutic window (the region of the visible spectrum located from 630 nm to 1000 nm, where damage to human tissues is not important) [26, 27], high singlet oxygen quantum yield [28, 29], photostability [27, 30], no dark toxicity [31], also a good balance are needed between hydrophobic and hydrophilic properties of the photosensitizers that could help them to better locate at cellular level [32]. So, it should be possible to direct the photosensitizers to different cell components by “controlling” the peripheral groups at the porphyrinic macrocycle, while keeping unchanged, or even improving their photochemical properties. [32–35].

In the present work the photophysical properties and the singlet oxygen quantum yields of the unsymmetrically substituted mesoporphyrins presented in Scheme 1 were investigated. In the same scheme we further present the structure of their parent symmetrical tetrasubstituted porphyrins. This series of new unsymmetrically substituted mesoporphyrins allows a different charge distribution over the periphery of the tetrapyrrolic macrocycle and consequently creates the possibility of controlling the transport of the photosensitizer molecule and its location at the cellular level without significant change of spectroscopic and photosensitizing properties [33]. The new structures suggest an unsymmetrical charge distribution over the macrocycle periphery of the tetrapyrrolic ring, so that the porphyrinic molecule gets a slight amphoteric character that favors the transport of the photosensitizer to the cellular targets, both in polar (the external environment of the cell) and nonpolar (the lipidic double layer of the cellular membrane) media [32, 33].

2. Experimental Section

2.1. Materials. Commercially available chemicals were used received from Sigma-Aldrich. All solvents were Merck *pro analysis* and were used without further purification.

Synthesis of the Unsymmetrically Substituted Mesoporphyrins. The unsymmetrically substituted mesoporphyrins under-study were synthesized according to the methods proposed by Adler et al. [36] and Little et al. [37] and recently adapted by the authors [38, 39]. Metal containing porphyrins were also already synthesized by us [40, 41] using the same method. After synthesis they were separated by column chromatography (with Al_2O_3 and silica gel as stationary phases and chloroform or benzene as eluent) and then

characterized by ^1H and ^{13}C NMR, UV-Visible and IR spectrometry [38–41].

Sample Preparation. Solutions in benzene of the compounds with optical densities at $\lambda = 377$ nm ($\text{OD}^{377\text{nm}}$) varying from 0.30 up to 0.75 were used to study the different emission processes.

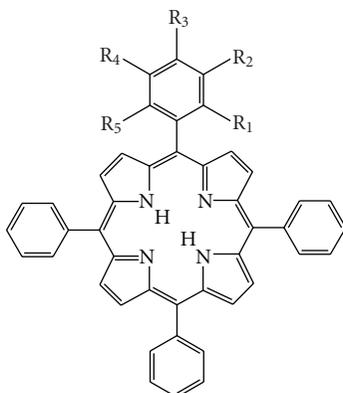

2.2. Methods.

Ground State Absorption. UV-Vis ground state absorption spectra were recorded using a Cary-OLIS 14 spectrophotometer. Further details are given elsewhere [42].

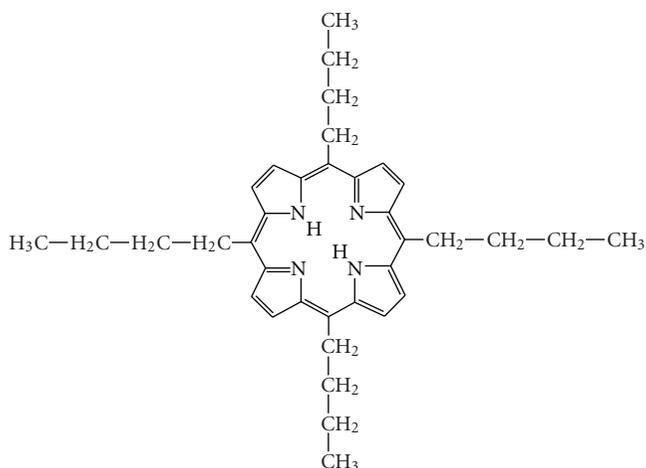

Time-Resolved Laser-Induced Luminescence (LIL) System. A schematic diagram of the LIL system is presented in [42, 43]. Laser-induced luminescence experiments were carried out with an N_2 laser (PTI model 2000, ca. 600 ps pulses, 1.6 mJ per pulse). The light arising from the irradiation of the sample by the laser pulse is collected by a collimating beam probe coupled to an optical fiber (fused silica) and is detected by a gated intensified charge coupled device (Andor ICCD detector, based on the Hamamatsu S5769-0907). The ICCD was coupled to a fixed imaging compact spectrograph (Oriol, model FICS 77441). The system could be used either by capturing all light emitted by the sample or in a time-resolved mode by using a delay box (Stanford Research Systems, model D6535). The ICCD has high speed (2.2 nanoseconds) gating electronics and intensifier and works in the 200–900 nm wavelength range.

Time-resolved emission spectra were available in the nanosecond to second time, so in order to evaluate the luminescence behavior of the compounds, time-resolved luminescence experiments were carried out for time delays from 0 to 20 nanoseconds ($\Delta t = 5$ nanoseconds) and for time delays from 50 to 250 μs ($\Delta t = 50 \mu\text{s}$), respectively, in the presence and in the absence of oxygen, at 77 K and 298 K. The photophysical properties measured in the presence of oxygen were evaluated from air equilibrated samples, and those measured in the absence of oxygen were evaluated from argon purged samples. Emission spectra may evidence some background which varies with the number of accumulations and the gain of the intensifier used to collect each time-resolved spectrum therefore, the *Y*-axis of each emission spectrum is labeled as luminescence intensity, arbitrary units.

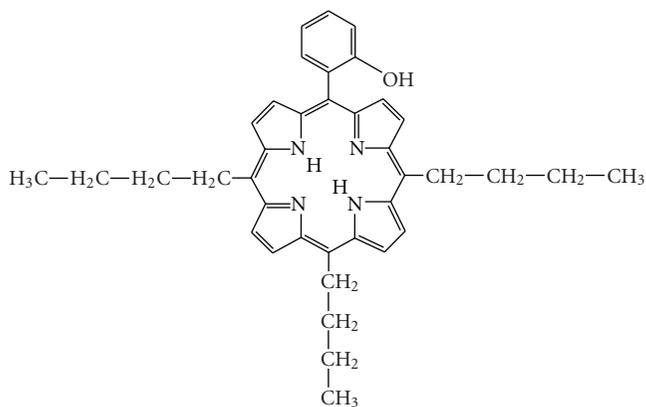

System for Measuring Singlet Oxygen Luminescence. A schematic diagram of the experimental set up used for measuring singlet oxygen is presented in Figure 1. Singlet oxygen experiments were performed at room temperature with a PTI-PL2300 nitrogen laser (337.1 nm, ca. 600 ps pulses, ~ 1.6 mJ/pulse) with air equilibrated samples [19]. The emission from singlet oxygen at $\lambda = 1270$ nm was detected at 90 degrees to the incident laser beam—after passing through a 1270 nm interference filter (*Corion*) or a combination of long-wave pass filters (1000 nm, 1100 nm, 1200 nm, *CVI Laser Corp.*) to reduce as much as possible the scattered radiation from the laser (shortly after the laser

by 337.1 nm N₂ laser pulses. The resultant emission curves were fitted with a single-exponential function to obtain the initial luminescence intensity at time $t = 0$ (or the intensity at any other time t) after the laser pulse [19, 44, 45]. The laser energy was varied using a series of calibrated neutral density filters (85.1%, 76.7%, 62.6%, 49.3%, 37.5%, 30.4%, 24.1%, 18.4%, and 12.8%).

3. Results and Discussion

3.1. Ground State Absorption. The UV-Vis absorption spectra of all porphyrins were measured in benzene, at room temperature. Figure 2 presents the absorption spectra for TBP and TBPOH_O, which are very similar to those of TPP and TPPOH_x ($x = \text{ortho-}, \text{meta-}, \text{para-}$) [39], with their Soret band (42 nm) and four Q bands (514–516 nm, 548–550 nm, 590–592 nm, and 648–652 nm), characteristic of D_{2h} symmetry class. In the investigated range of concentrations 10^{-6} – 10^{-5} M) no aggregate formation was observed.

The ground state absorption results are in full accordance with the evaluation of the electronic transitions made on the basis of the conformational structures obtained with HYPERCHEM [33], that already predicted that the substitutions made at TPP and TBP periphery's (phenyl at ortho-, meta-, para-positions) will not affect too much the

spectral properties of the new compounds (and possibly also not affect their photosensitizing properties [2]).

3.2. Fluorescence Emission and Fluorescence Quantum Yield.

In this study we intend to characterize the luminescent properties of the new unsymmetrically substituted mesoporphyrinic compounds in order to evaluate their importance as photosensitizers in photodynamic therapy. Figure 3 shows the corrected laser-induced fluorescence spectra for TPP, TPPOH_x ($x = \text{ortho-}, \text{meta-}, \text{para-}$), TBP, and TBPOH_O. For each porphyrin the fluorescence spectra were registered for different concentrations (more precisely for optical densities from 0.30 to 0.75 at the laser excitation wavelength, 337 nm) and no significant changes on the spectral shape with concentration were detected (data not shown).

The shape of the spectra presented by the dyes is characteristic of the emission of the porphyrin free base [25]. All fluorescence spectra of the compounds investigated seem to keep this particular shape, with two bands located in the spectral region of 650–750 nm (see Table 1). Furthermore, the presence of the –OH group in only one of the ortho-, meta- or para-positions of phenyl ring leaves the fluorescence spectrum practically unchanged, when compared to that of the reference compound, TPP. This is not the case for the substitutions at meso-positions of porphyrinic

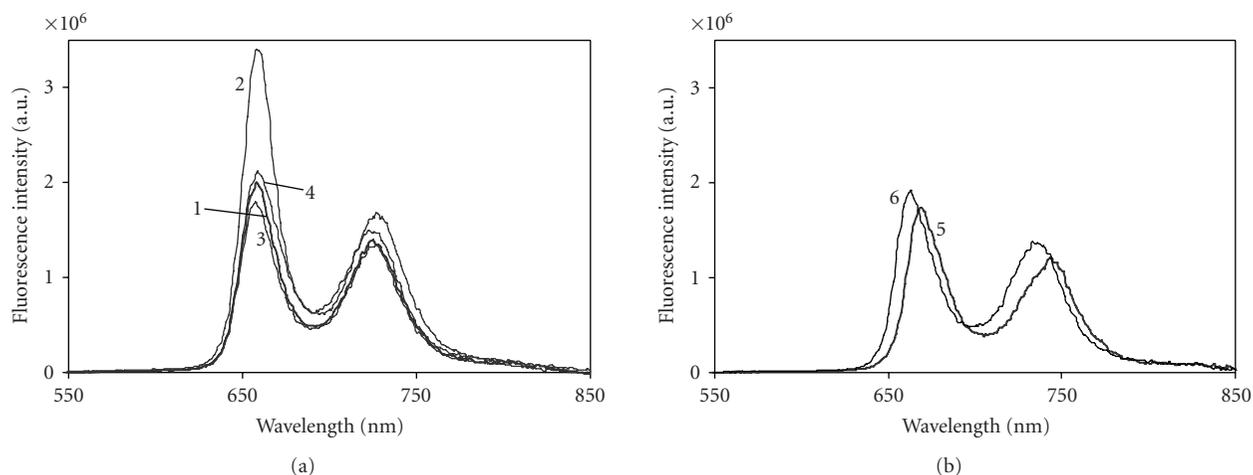

FIGURE 3: Laser-induced corrected fluorescence emission spectra of (a) TPP (*curve 1*), TPPOH_O (*curve 2*), TPPOH_M (*curve 3*), and TPPOH_P (*curve 4*) and of (b) TBP (*curve 5*) and TBPOH_O (*curve 6*) in benzene, at room temperature. The optical density at the excitation wavelength was always 0.30 and the samples were air equilibrated.

TABLE 1: Wavelength maximum of the fluorescent emission bands, λ , and fluorescence quantum yield, Φ_F , for the series of unsymmetrically substituted mesoporphyrins in benzene for air equilibrated samples.

Compound	λ (nm)		Φ_F
TPP	661	726	0.13*
TPPOH _O	660	728	0.10 ± 0.04
TPPOH _M	660	728	0.09 ± 0.03
TPPOH _P	660	728	0.13 ± 0.02
TBP	670	745	0.08 ± 0.03
TBPOH _O	664	738	0.08 ± 0.03

* From [44].

macrocycle: from TPP to TBP, the differences between the positions of fluorescence emission bands are approximately 10 and 20 nm, respectively, (661 and 726 nm for TPP; 670 and 745 nm for TBP). As can be seen from Figure 3 and Table 1, after changing a butyl group by a hydroxyphenyl group (going from TBP to TBPOH_O), the observed effect is the same, although with a smaller extension. In this case, the difference is still relevant (664 and 738 nm for TBPOH_O).

The fluorescence quantum yields, ϕ_F , were determined according the equation, $\phi_F^x = \phi_F^0(S^x/S^0)$ [42, 46], where x and 0 refer to the compound under study and to the standard, respectively, and S is the integrated area of the corrected emission spectra. The values of fluorescence quantum yields were determined relatively to TPP ($\phi_F = 0.13$ [47]) and are presented in Table 1.

From the analysis of these values, it can be seen that TPP and TPPOH_P showed the highest fluorescence quantum yield, 0.13, contrary to butyl-substituted compounds (TBP and TBPOH_O), which exhibited the smallest value in this series, 0.08. The fact that the values of fluorescence quantum yield determined are generally low for all the investigated porphyrins shows that fluorescence is not the main radiative

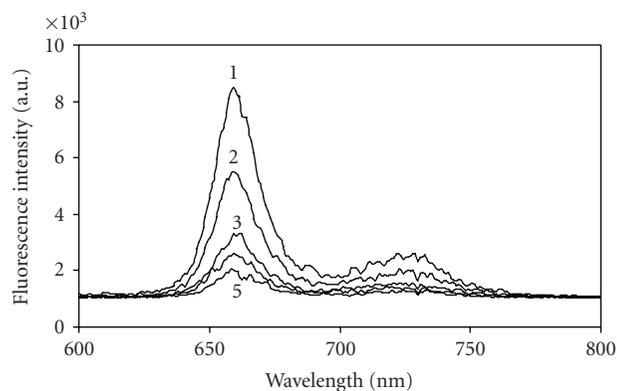

FIGURE 4: Time-resolved laser-induced fluorescence emission spectra of TPPOH_O in benzene at room temperature registered 0, 5, 10, 15, and 20 nanoseconds (resp., curves 1 to 5) after laser pulse, at 337 nm. The spectrum was registered with a gate of 100 nanoseconds for air equilibrated samples.

deactivation pathway to the ground state. This indicates that triplet state population may be significant and if that is the case, the quantum yield for singlet oxygen generation is probably high as well. This fact allows us to anticipate promising photosensitizing properties for the new compounds.

Time-resolved laser-induced fluorescence emission experiments were carried out for all the porphyrins in benzene. The results were very similar for all the compounds investigated. Figure 4 shows a representative result for TPPOH_O; fluorescence curves registered 0, 5, 10, 15, and 20 nanoseconds after the laser excitation pulse, at 337 nm.

From time-resolved fluorescence measurements it was possible to estimate singlet state fluorescence lifetimes, τ_S , which is also an important parameter to characterize the fluorescent properties of the new porphyrinic compounds [48].

TABLE 2: Fluorescence lifetime, τ_S , for the series of unsymmetrically substituted mesoporphyrin compounds in benzene and in the presence of oxygen (air equilibrated samples) and in the absence of oxygen (argon purged samples).

Compound	τ_S (ns)		k_S ($\text{mol}^{-1} \text{s}^{-1}$) $\times 10^{-9}$
	With O ₂ (air equilibrated)	Without O ₂ (argon purged)	
TPP	9.7	10.8	10.9
TPPOH _O	9.4	9.8	5.4
TPPOH _M	9.5	10.5	10.2
TPPOH _P	9.8	10.6	7.3
TBP	9.6	9.8	2.0
TBPOH _O	9.3	9.4	0.5

Table 2 shows τ_S for each compound under study, in the presence and in the absence of oxygen.

The rate constant of singlet state quenching by molecular oxygen, k_S , was also determined according the equation [25]:

$$k_S = \frac{(\tau_S)^{-1} - (\tau_S^0)^{-1}}{[\text{O}_2]} \quad (1)$$

where τ_S^0 and τ_S are, respectively, the singlet state fluorescence lifetimes of the compound in solution in the absence and in the presence of oxygen.

All the air equilibrated solutions of the porphyrins under study present very similar singlet state fluorescence lifetimes ranging from 9.3 to 9.8 nanoseconds (mean value of τ_S (with O₂, air equilibrated samples) = 9.6 ± 0.3 nanoseconds), which only slightly increase in the absence of oxygen, for the argon purged samples, from 9.4 to 10.8, (mean value of τ_S (without O₂, argon purged samples) = 10.1 ± 0.6 nanoseconds), implying a small rate constant of singlet state quenching by molecular oxygen, as actually was found (see Table 2). This value of mean singlet state fluorescence lifetime is very close to the value reported for TPP in toluene [25]. Ortho derivatives seem to present slightly shorter lifetimes relative to their parent porphyrins, as can also be observed from Table 2.

3.3. Delayed Fluorescence. Time-resolved laser-induced emission experiments on longer time scales, carried out for air equilibrated samples both at room temperature and 77 K, showed that the phosphorescent emission of this series of compounds is negligible (result not shown). This is in agreement with the values reported in the literature for this class of compounds ($\Phi_P \approx 10^{-5}$) [25, 47].

However with these experiments another process was also evidenced: for all the compounds under study, 1 μs after the laser pulse, and in the absence of the molecular oxygen (argon purged samples), it was still possible to measure spectra similar to those of the fluorescence emission, as can be observed at Figures 5(b) and 5(e) to be compared with Figures 5(a) and 5(d) and also Figures 3 and 4. Figure 5 presents results for TPP and TBP in benzene, but very similar results were observed for all the other porphyrins under study.

TABLE 3: Delayed fluorescence lifetime, τ_{DF} , for the series of unsymmetrically substituted mesoporphyrins in benzene (at room temperature, in the absence of oxygen) (argon purged samples).

Compound	τ_{DF} (μs) T = 293 K	τ_{DF} (μs)* T = 77 K
	Without O ₂ (argon purged)	Without O ₂ (argon purged)
TPP	12.0	74
TPPOH _O	9.3	—
TPPOH _M	9.1	—
TPPOH _P	11.4	—
TBP	12.8	—
TBPOH _O	12.6	—

*The intensities of the emission bands at T = 77 K for the compounds presented in the table were very small, so that TPP was the only one for which the intensity was sufficiently high to allow an acceptable precision for the delayed fluorescence lifetime determination.

At such long time delay all of the directly excited fluorescence was extinguished [48]. The intensities of these new emission bands are smaller (ten times in amplitude) than the ones belonging to true fluorescence spectra (compare intensities from Figures 5(a) and 5(b) for TPP or from Figures 5(d) and 5(e) for TBP). The fact, that these spectra are located at the same wavelengths as those of fluorescent emission (from 650 to 750 nm), and in a different wavelength region from that of the typical phosphorescence (800 to 950 nm) from porphyrins, pointed out to the existence of a delayed fluorescence process [25, 47] (see Figure 5(b)). In the presence of the molecular oxygen (air equilibrated samples) these long-lived emissions were not observed (see Figures 5(a) and 5(d)).

When the measurement of these long emissions was carried out at lower temperatures (T = 77 K), the intensity of the emission process was visibly reduced, becoming almost undetectable for TPPOH_O, TPPOH_M, TBP (see Figure 5(f)), and TBPOH_O. This result, presented at Figures 5(c) and 5(f), respectively, for TPP and TBP, shows that this is a thermally activated or *E-type* delayed fluorescence process [48]. The higher values of the temperature allowed the population of the higher-energy levels, so that the electronic transfer from the first excited triplet, T₁, to the first excited singlet, S₁, (reverse ISC) was favored. Consequently, the T₁ quenching controls the quenching rate of S₁, to the ground state, S₀, (fluorescence). The process of delayed fluorescence quenching by molecular oxygen is always predominant, being limited only by the solubility of molecular oxygen in a particular solvent [48]. The values of the delayed fluorescence lifetime, τ_{DF} , are presented in Table 3.

Although the values observed do not vary too much within the series, TBP and TBPOH_O display slightly longer delayed fluorescence lifetimes and so higher values of singlet oxygen generation quantum yields could be expected. The reason for that is evident: a higher τ_{DF} means that the molecule stays longer in the first excited triplet, T₁, and consequently there is a higher probability of the energy to transfer to the ground state of the oxygen molecule. As we will see in the next section this was observed in fact.

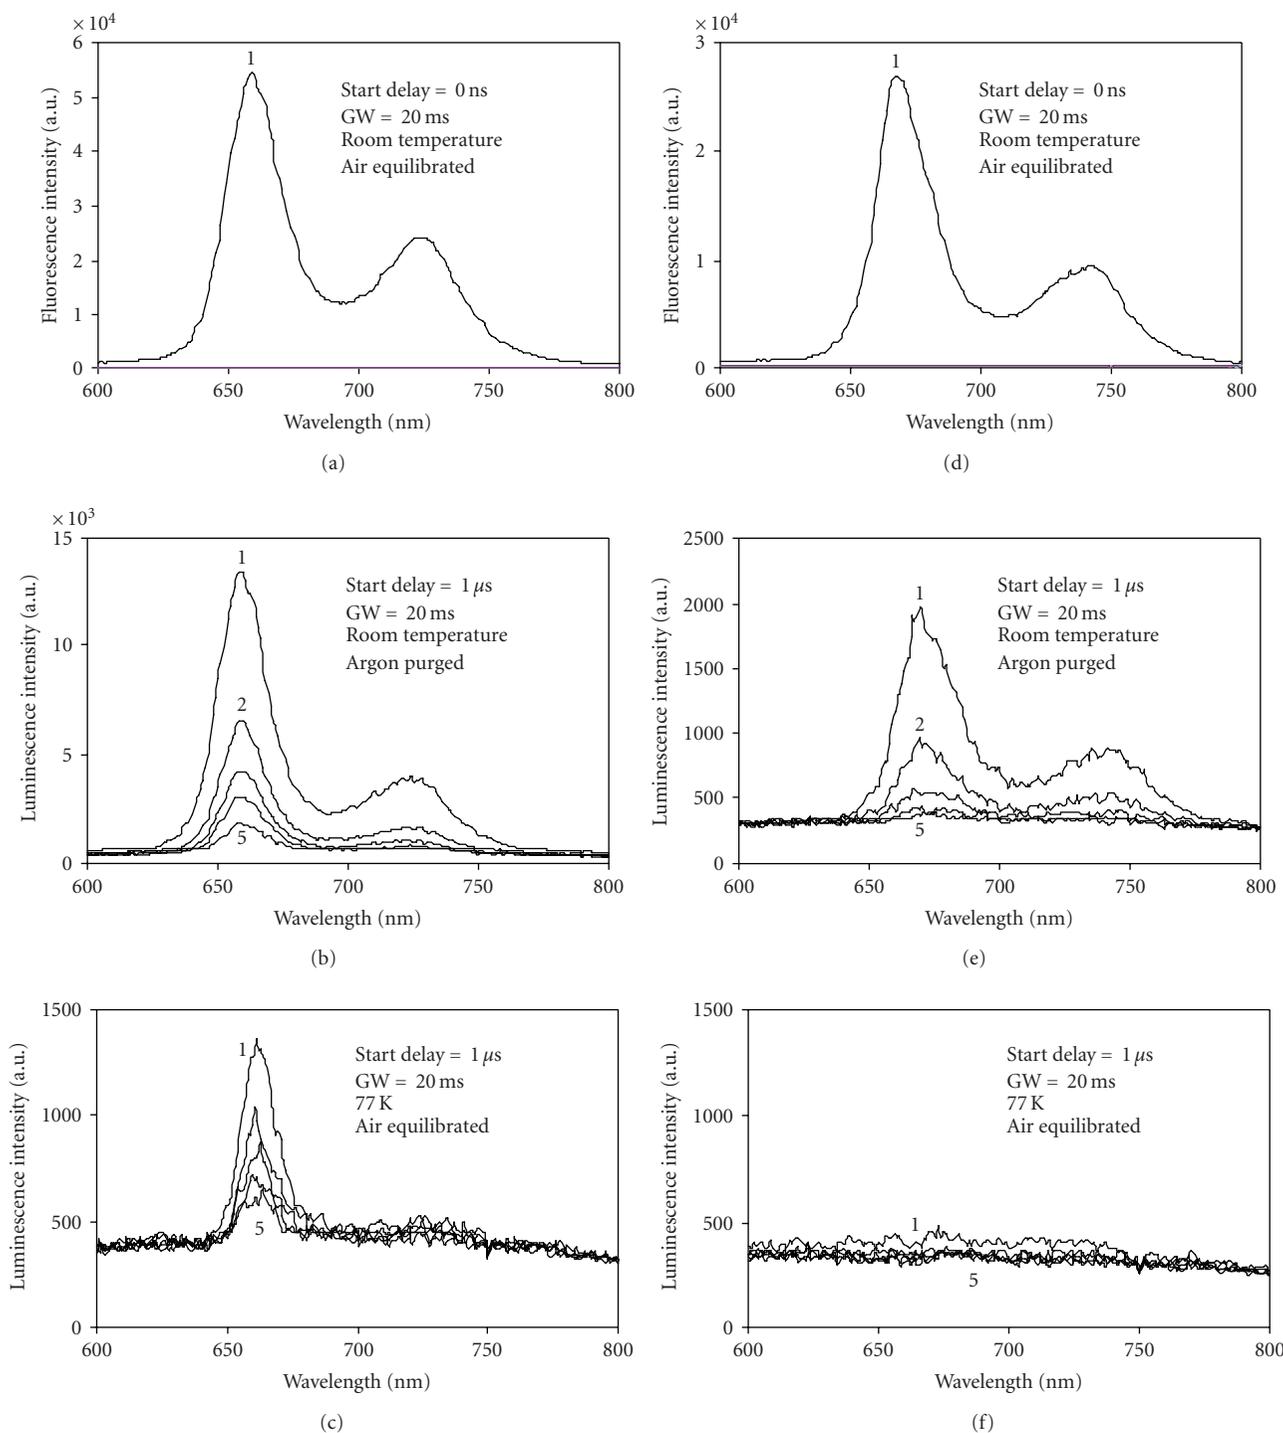

FIGURE 5: Time-resolved laser-induced luminescence emission spectra of TPP (left column) and TBP (right column) in benzene. Spectra were registered with a 20 ms gate with at (a), (d) room temperature, in presence of O_2 (air equilibrated samples), (b), (e) room temperature, in absence of O_2 (argon purged samples), (c), (f) $T = 77$ K, in presence of O_2 (air equilibrated samples), (50, 100, 150, 200 and 250 μ s, after laser pulse, resp., for curves 1 to 5 at 337 nm). The start delay was zero in (a) and (d) and 1 μ s in (b), (c), (e), and (f).

3.4. Efficiency of Singlet Oxygen Photogeneration. As it was said before the photosensitized generation of the singlet oxygen was the main motivation for the synthesis of these new compounds, mainly because the role that these species play in photodynamic therapy of cancer (PDT).

Phenazine in benzene ($\phi_{\Delta \text{Phz}} = 0.83$) and 5,10,15,20-tetraphenyl-21,23-H-porphine in benzene ($\phi_{\Delta \text{TPP}} = 0.66$) [44] with an optical density of 0.30 [45] at the excitation wavelength (337 nm) were used as references. For references and samples with matching optical densities

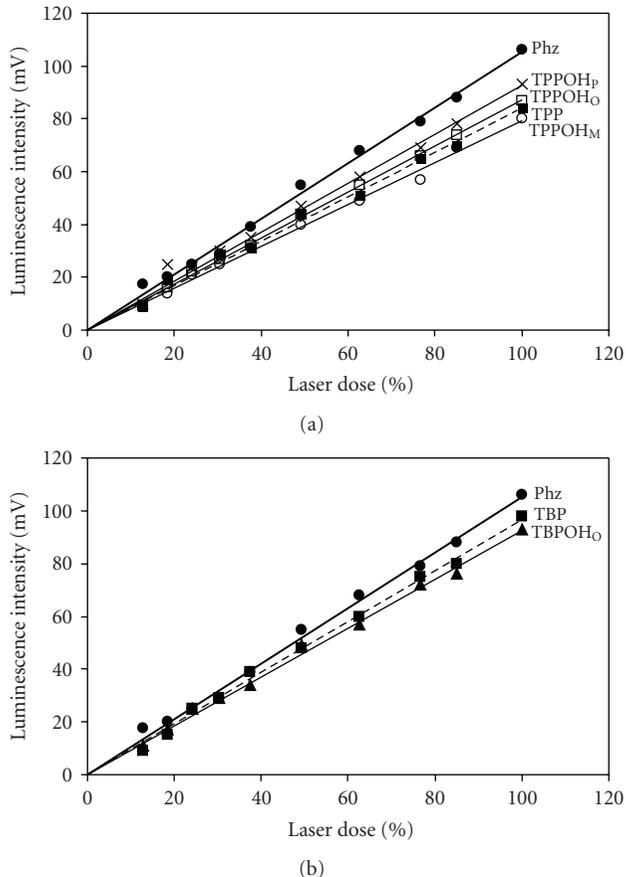

FIGURE 6: Plots of initial singlet oxygen ($^1\text{O}_2$) luminescence intensity versus laser dose percentage for optically matched samples (O.D. = 0.30) of (a) Phenazine, (TPP (---), TPPOH₀, TPPOH_M, and TPPOH_P) and (b) Phenazine (—), TBP (---) and TBPOH₀. Air equilibrated samples in benzene at room temperature; excitation wavelength was 337 nm.

($\text{OD}^{337\text{ nm}} = 0.30$) accurate calibration curves with linear dependence of singlet oxygen emission intensity versus laser energy were obtained by placing neutral density filters in the excitation laser path length. A comparison of the slopes for the samples under study and for the reference yielded ϕ_{Δ}^x in a straightforward manner, that is, $\phi_{\Delta}^x = \phi_{\Delta}^0$ ($\text{slope}_x/\text{slope}_0$), where x and 0 refer, respectively, to the compound under study and to the standard, as presented in Figure 6. Alternatively, $\phi_{\Delta}^x = \phi_{\Delta}^0(I_x/I_0)$, where I is the intensity of luminescence at time t , can also be used [19, 44, 45]. On this range of concentrations there was no dependence on concentration of the quantum yield of singlet oxygen production. The values of the singlet oxygen quantum yields, Φ_{Δ} , obtained in this study are shown in Table 4.

From the analysis of the singlet oxygen quantum yields a first observation can be made: similar or even higher values of singlet oxygen quantum yields were found for all the new compounds in comparison to those of the reference, TPP. Thus attempts to control the charge density at the macrocycle

TABLE 4: Singlet oxygen quantum yields, Φ_{Δ} , and photodynamic efficiency, α , for the series of unsymmetrically substituted mesoporphyrins in benzene for air equilibrated samples, at room temperature.

Compound	Slope	Φ_{Δ}	α (mole/second) at λ_{acc}	
			633 nm	650 nm
TPP*	0.84	0.66 ± 0.05	9.99	43.07
TPPOH ₀	0.87	0.69 ± 0.04	9.38	53.73
TPPOH _M	0.79	0.62 ± 0.04	8.32	31.78
TPPOH _P	0.93	0.73 ± 0.03	10.58	40.51
TBP	0.96	0.76 ± 0.03	10.49	20.04
TBPOH ₀	0.93	0.73 ± 0.02	5.19	18.31
Phz*	1.05	0.83	—	—

* Used as reference compounds ($\phi_{\Delta}^{\text{Phz/Benzene}} = 0.83$; $\phi_{\Delta}^{\text{TPP/Benzene}} = 0.66$ [44].)

periphery did not affect visibly the photosensitizing properties of the compounds, and sometimes these properties were even improved.

From the analysis of the delayed fluorescence lifetimes, τ_{DF} , it can be observed that singlet oxygen quantum yields are higher for the compounds having high values of τ_{DF} . Moreover, the magnitude of the sequence τ_{DF} is very similar to that of Φ_{Δ} . We concluded that therefore the more the population of the first triplet state, T_1 , is significant, the higher the probability of the energy transfer from the photosensitizer porphyrin, to the oxygen, with the consequent production of singlet oxygen is.

3.5. Evaluation of the Photodynamic Efficiency. Table 4 presents also the calculated values of the photodynamic efficiency factor, α . The intrinsic efficiency of the photodynamic process can be quantified by the photodynamic efficiency factor, α , which is defined by the yield of singlet oxygen generation (mole/second) for the incident power unity density (W/cm^2), at the specific irradiation wavelength on the concentration unit of the photosensitizer, according to $\alpha = 1.925 \times 10^{-5} \cdot \lambda \Phi_{\Delta} \epsilon_s$, where λ is their radiation wavelength, in nm, and ϵ_s the photosensitizer molar absorption coefficient, in $\text{M}^{-1}\text{cm}^{-1}$ [49, 50].

We can observe the difference between the estimations of the photosensitization activity on the basis of singlet oxygen quantum yields, Φ_{Δ} , and those on photodynamic efficiencies, α : at the wavelengths where the human tissues are irradiated within ordinary PDT protocols (620 to 670 nm), compounds showing higher Φ_{Δ} , like TBP or TBPOH₀, presented lower values of α . This is because, besides Φ_{Δ} contribution, this parameter reflects also the contribution of the absorption coefficient of the photosensitizer at the irradiation wavelength. Furthermore, we have also to account for the value of the attenuation coefficient of the biological environment, at the specific wavelength of irradiation, $1/\mu_{\text{eff}}$. In fact in a PDT treatment the ideal irradiation wavelength is a compromise between photodynamic efficiency and attenuation coefficient of the environment. Actually, even for deeper tissues, the later supposes higher efficiencies in case of use of radiations in the

red region of the spectra ($1/\mu_{\text{eff}}$ has values of 0.02, 0.95, 2.7, 1.2, resp., at 545, 633, 680, and 800 nm).

4. Conclusions

In this paper several unsymmetrically substituted mesoporphyrins (TPPOH_x, x = ortho-, meta-, or para- and TBPOH_O) were synthesized by a method recently adapted by the authors with the objective of promoting the amphoteric character of their molecular structures and in this way to improve their capacity of being transported to different cellular targets without losing the good singlet oxygen sensitizing properties of their parent compounds, the nonsubstituted mesoporphyrins (TPP and TBP). Ground state absorption and fluorescence emission properties were not significantly affected by the unsymmetrical substitution. Fluorescence quantum yields and fluorescence lifetimes were of the same order of magnitude of those of TPP and TBP. Furthermore a delayed fluorescence process was observed for all the compounds investigated. Singlet oxygen quantum yield determination confirmed that the initial objectives of the work were largely achieved since the unsymmetrically substituted mesoporphyrins under evaluation presented singlet oxygen quantum yields of the same order of the magnitude or even larger than TPP. The evaluation of the photodynamic efficiency factor clearly illustrated that the high singlet oxygen quantum yield of a photosensitizer is not a full warranty of its adequacy for PDT use.
