TiO$_{2-x}$N$_x$ powders with low N-doping concentrations (0.021 < x < 0.049) were prepared by annealing commercial TiO$_2$ (P-25) under an NH$_3$ flow at 550°C. Regardless of UV or visible case, the photoactivities of the samples decreased as x increased, and TiO$_{1.979}$N$_{0.021}$ showed the highest activity for the 4-chlorophenol (4-CP) decomposition under the visible-light irradiation. The visible-light response for N-doped TiO$_2$ could arise from an N-induced midgap level, formed above the valence band (O 2p). Electron spin resonance (ESR) measurements and the radical scavenger technologies gave the combined evidence that the active species (•OH and O$_2$•−) are responsible for the photodecomposition of 4-CP over TiO$_{2-x}$N$_x$ under the visible irradiation. A possible photocatalytic mechanism was discussed in detail.

1. Introduction

Semiconductor photocatalysis has been the focus of numerous investigations because of its application for the destruction of chemical contaminants and water splitting [1–5]. Among all the materials, TiO$_2$ remains the most promising owing to its superior photoreactivity, high corrosion resistance, and nonhazardous nature. Even so, the poor solar efficiency (maximum 5%) has hindered the commercialization of this technology [6–8]. Various approaches have been attempted to enhance the visible-light utilization of TiO$_2$. A classical example is the doping of TiO$_2$ with transition-metal elements [9, 10]. However, the doped materials have been shown to suffer from thermal instability, and the metal centers act as electron traps, which reduces the photocatalytic efficiency. Dye sensitization in photochemical systems has also been explored extensively [11, 12]. Dyes possessing carboxylate or hydroxyl functions, in particular, interact with the surface of TiO$_2$ particles, thereby providing the path for electron-transfer from the excited dye adsorbate to the semiconductor. Unfortunately, this technology cannot be practically used for detoxification of waste water since the photosensitizers may be gradually photodegraded and become less effective.

Recently, the band gap of TiO$_2$ has been narrowed successfully by doping with nonmetal cations, by replacing lattice oxygen with B, C, N, or S dopants [13–16]. It is widely recognized that anionic nonmetal dopants may be more appropriate for the extension of photocatalytic activity into the visible-light region, because the related impurity states are supposed to be close to the valence band maximum [17]. Furthermore, the position of the conduction band minimum, which must be kept at the level of the H2/H2O potential, when TiO$_2$ is used for the photoelectrolysis of water into hydrogen and oxygen, is not affected [17].

Among all the nonmetal cations, substitutional N-doping was found to be particularly effective in decreasing the band gap of TiO$_2$ through the mixing of N and O 2p states. The presence of nitrogen doping extends the optical absorption of TiO$_2$ to the visible-light spectrum and enhances the visible-light-driven photocatalysis [18–24]. Generally, N-doped TiO$_2$ samples have been produced by
different preparative procedures: (i) treating TiO$_2$ powder with NH$_3$ gas at high temperature (>500°C) followed by partial reoxidation in air [15, 17]; (ii) via “nitridation” of TiO$_2$ colloidal nanoparticles with alkylammonium salts at room temperature [18]; (iii) hydrolysis of NH$_x$TiO$_2$ mixtures to gain powder samples [20]; (iv) to produce carbon-substituted N-doped sample by a flame pyrolysis at high temperature [25]. The various N-doped TiO$_2$ catalysts have been applied to bleach methylene blue [18], split water [23], and oxidatively degrade 2-propanol [26], 4-CP [19], acetone vapors [27], and for the photokilling of harmful pathogens as well as peroxidation of the cell membrane of biomolecules [20]. Indeed, the visible-light-induced photocatalysis of the N-doped TiO$_2$ is effective.

However, it is quite debatable as to the origin of the visible-light responses for N-doped TiO$_2$ to date. On the basis of a theoretical analysis, Han et al. [15] suggested that visible-light responses for N-doped TiO$_2$ arose from band narrowing by mixing of N 2p and O 2p orbitals. Irie et al. [26] insisted that visible light sensitivity of N-doped TiO$_2$ was due to an isolated N 2p state rather than the narrowing of the band gap. Further, Lindgren et al. [28] reported that N 2p was situated close to the valence band maximum by using the photoelectrochemical measurements and that the conduction band edge remained unchanged by N-doping. Ihara et al. [27] argued that the oxygen vacancies were contributed to the Vis activity and the doped N atoms only enhance the stabilization of these oxygen vacancies.

Another question relates to the photodegradation mechanism involved in the N-doped TiO$_2$ photocatalysis. It has been reported that a variety of organic compounds are mineralized into CO$_2$ and inorganic species on N-doped TiO$_2$ under visible-light illumination [18, 19, 26]. However, it still remains conjectural whether the certain product comes from a direct reaction with photogenerated holes or via reactions with surface intermediates of the water photooxidation reaction. It is thus quite difficult to get definite conclusions on the reaction mechanism. An examination of the formation of active oxygen species can provide useful information about the fate of the valence hole and the conduction electrons, and lead to a greater understanding of the visible-induced photocatalysis by N-doped TiO$_2$ in general.

In the previous work, we have already observed the photocatalytic process mediated by N-doped TiO$_2$ using an ESR technique [29]. In this report, to further observe the mechanism of this photocatalytic system, N-doped TiO$_2$ powders were firstly prepared by annealing the commercial P-25 (TiO$_2$) in NH$_3$ flow at 550°C. The samples were characterized by X-ray photoelectron spectroscopy (XPS), X-ray diffraction (XRD), and UV-Vis diffused reflection spectrum (DRS). 4-CP decomposition was used as a probe reaction to evaluate the photocatalytic activities of these powders under UV and Vis irradiation. The formation of active oxygen species was detected by spin-trap electron spin resonance (ESR) techniques and the radical scavenger technologies to provide an overall understanding of the reaction mechanisms.

2. Experimental Section

2.1. Materials. Commercial P-25 (Degussa, 50 m$^2$ g$^{-1}$, 75% rutile, and 25% anatase) was treated in a flow reactor system in an N$_2$ gas atmosphere (1 atm) at 550°C. For doping, the N$_2$ flow was replaced by NH$_3$ for 5–25 min after the target temperature had been reached. Subsequently, the crystals were kept in flowing N$_2$ for 1 h at 550°C and then cooled in flowing N$_2$. For comparison, undoped P-25 was also annealed under N$_2$ flow at 550°C for 25 min as a reference sample.

The spin trap 5, 5-dimethyl-1-pyrroline-N-oxide (DMPO) was kindly supplied. Stock solutions of DMPO in deaerated water were prepared under argon and stored in the dark bottles at ~20°C. All chemicals were reagent grade and used without further purification. Deionized and doubly distilled water were used throughout this study.

2.2. Characterization. XPS analysis was obtained using a PHI 5300 ESCA instrument with an Al Kα X-ray source at a power of 250 W. The pass energy of the analyzer was set at 35.75 eV and the base pressure of the analysis chamber was <3 × 10$^{-9}$ Torr. The binding energy scale was calibrated with respect to the C 1s peak of hydrocarbon contamination fixed at 285.0 eV. According to Irie et al. [26], the peak at 396 eV is derived from Ti-N bonds. Therefore, the x values (nitrogen concentrations) in TiO$_2$–xN$_x$ were estimated by comparing to the product of the 396 eV peak area multiplied by the nitrogen sensitivity factor to the product of the 531 eV peak area (O 1s, Ti–O bonds) multiplied by the oxygen sensitive factor. XRD patterns of the powders were recorded by a Bruker D8 Advance X-ray diffractometer by using Cu Kα radiation and a 2θ scan rate of 2° min$^{-1}$. UV-Vis DRS was obtained by using a Hitachi U-3010 spectrometer.

2.3. Photoreactor and Light Source. The photocatalytic activities were evaluated by the decomposition of 4-CP when irradiated with UV (λ = 254 nm) and Vis light (λ > 420 nm). UV light was obtained by a 12 W Hg lamp (Institute of Electric Light Source, Beijing) and the average light intensity was 150 μW cm$^{-2}$. In the case of Vis light irradiation, a 500 W xenon lamp (Institute of Electric Light Source, Beijing) was focused through a window, as a 420 nm cutoff filter was placed onto the window face of the cell to ensure the desired irradiation light. The average light intensity was 30 mW cm$^{-2}$. The irradiation area was approximately 40 cm$^2$. The radiant flux was measured with a power meter from the Institute of Electric Light Source (Beijing, China).

2.4. Procedures and Analyses. Aqueous suspensions of 4-CP (usually 100 mL, 10 mg L$^{-1}$) and 0.1 g of the catalysts were placed in a vessel. Prior to irradiation, the suspensions were magnetically stirred in the dark for ca. 30 min to ensure the establishment of an adsorption/desorption equilibrium. The suspensions were kept under constant air-equilibrated conditions before and during the irradiation. At given time intervals, 3 mL aliquots were sampled and centrifugated to remove the particles. The filtrates were analyzed by recording variations in the absorption band (224 nm) in the UV-Vis
3. Results and Discussion

3.1. Sample Characterization. XRD patterns of the as-prepared samples are shown in Figure 1. Degussa P-25 nanopowder sample, though dominantly of the anatase form, also contains some notable contribution from the rutile structure (ratio approximately 3:1) [18]. Replacing an O atom with an N atom in TiO₂ does not result in significant structural changes, although the N atom has a larger ion radius (0.171 nm) than that of the O atom (0.132 nm) [24]. Ti–N bond length, 1.964 Å, is only slightly longer than that of Ti–O, 1.942 Å. Therefore, the structural modifications due to the N doping are relatively minor [30]. This could also be understood that the concentration of the doped N atom (given later) might be low to cause a shift.

Global XPS profiles for the as-prepared samples are shown in Figure 2(a). According to XPS spectra, the samples contain only Ti, O, and N atoms. And binding energies for O 1s, Ti 2s, Ti 2p, and C 1s are 533.2, 576.3, 473.5, and 285.0 eV, respectively. Figure 2(b) shows the N 1s spectra of the as-prepared samples. A new peak at 396 eV was observed, which is generally considered as evidence for the presence of Ti–N bonds, suggesting that the oxygen sites were substituted by nitrogen atoms [26]. In contrast, N₂ gas annealed samples did not display a peak at 396 eV. The peak at 400 eV could be ascribed to N atoms from adventitious N₂, NH₃, or N-containing organic compounds adsorbed on the surface [18]. The estimated x values from the XPS spectra were 0.021, 0.029, 0.035, 0.041, and 0.049 for the samples prepared at NH₃ flow for 5, 10, 15, 20, and 25 min, respectively. Various forms of N-doped TiO₂, including powders, films, and nanoparticles, have been investigated by XPS [17–19, 31–33]. In most cases, a peak at 396–397 eV was detected and attributed to substitutional nitrogen doping given the proximity to the typical binding energy of 397 eV in Ti–N [31]. However, in a few recent papers, this feature was found to be completely absent while the peaks at higher binding energies (399–404 eV) were observed [19, 32]. In some other cases, both features have been observed [17, 24, 33]. Since the peaks for nitrites and nitrates fall at a very high binding energy (407–408 eV), nitrogen species in doped TiO₂ are expected to be in a lower oxidation state [33].

3.2. Photoabsorbance Properties and Band Structures. Figure 3 shows UV-Vis DRS of TiO₂−ₓNₓ and TiO₂. Noticeable shifts of the absorption shoulders into the Vis-light region were observed for TiO₂−ₓNₓ. This absorption shoulder at 400–550 nm is related to the presence of nitrogen since it increases with nitrogen content. Additionally, the absorption edge of new band well agrees with the reported value for the N-doped TiO₂ system [19, 24]. These samples, after they have been doped, are pale-yellow in color, and the colors were darker gradually as x increased whereas the undoped sample is white. The color of the N doping samples are partially due to the bulk reduction of the crystal, because the thermal decomposition of NH₃ on the TiO₂ surface results in the evolution of molecular hydrogen, which reduces the crystal electronically [17]. In addition, the presence of the Vis absorption band indicates that nitrogen penetrates into the single crystal and effectively changes the electronic structure of TiO₂ [17, 26]. TiO₂ is an indirect gap semiconductor, and the band gaps of the TiO₂−ₓNₓ and TiO₂ can be estimated from tangent lines in the plots of the square root of the Kubelka-Munk functions against the photon energy [26], as shown in the insert of Figure 3. The tangent lines, which are extrapolated to α₁/2 = 0, indicate the band gaps of TiO₂−ₓNₓ and TiO₂ are Eg = 2.95 eV.

In the present study, the electronic structure of N-doped TiO₂ was newly investigated by DFT calculations. We optimized the lattice parameters and atomic positions of TiO₂ by minimizing the total energy of anatase structure.
The atomic positions of N-doped TiO₂ were optimized based on the theoretical lattice constants of TiO₂ without imposing any symmetry. N doping was modeled by replacing 1 oxygen atom in the 20-atom anatase supercell, as shown in Figure 4. The resulting stoichiometry is TiO₂−ₓNx with 𝒙 = 0.149. The DOS results of TiO₂ were shown in Figure 5(a). The occupied bands of TiO₂ were classified into four bands. The lower-energy side in the occupied bands consisted of solely Ti 4s (1∼2#). The middle part of the occupied bands consisted of Ti 3p orbitals (3∼8#) and O 2s orbitals (9∼16#), respectively. The higher-energy side, that is, corresponded to the valence band (VB), consists of O 2p orbitals (13∼24#). The bottom of the conduction band (CB) was formed by the Ti 3d orbitals, with a small contribution of the O 2p (25∼34#); the top of CB was formed by the Ti 3d orbitals (35∼36#). Thus, the highest occupied and lowest unoccupied molecular orbital levels were composed of the O 2p and Ti 3d orbitals, respectively. The band gap of TiO₂ was estimated to be 2.27 eV. Generally, the band gap calculated by DFT is smaller than that obtained experimentally, which is frequently pointed out as a common feature of DFT calculations [34]. The DOS result of N-doped TiO₂ were shown in Figure 5(b). One can see that the VB of N-doped TiO₂ is composed of the hybrid orbitals of O 2p and N 2p. The calculated band gap of TiO₂ was narrowed by 0.41 eV due to the N doping. Asahi et al. calculated by the band structure of TiO₂−ₓNx, where 𝒙 = 0.25 and 0.12, that is, when 12.5 and 6% of the oxygen sites were substituted by nitrogen, and reported that mixing the N 2p and O 2p states narrowed the band gap. The present DOS calculation is in agreement with their conclusion. However, it keenly contradicts with the UV-Vis spectra of N-doped TiO₂ (Figure 3), which showed N-doping did not narrow the band gap of TiO₂ [15].

Figure 5: Total DOS: (a) TiO$_2$ (anatase), (b) N-doped TiO$_2$.

The procedure of including more N atoms in the same supercell is more accurate than using smaller unit cell as it allows a direct comparison of the various levels of doping on the band structure of the material. Valentin et al. [30] calculated the band gap of TiO$_{2-x}$N$_x$ with $0.031 < x < 0.094$ by modeling the 96-aom supercell replaced by 1, 2, or 3 nitrogen atoms. Their analysis of the electronic energy levels showed that N doping did not cause the shift of the position of both top and bottom of the O 2p valence band, as well as of the conduction band, with respect to the undoped material. This is in contrast with the conclusion of Asahi et al. [15]. Therefore, the N doping amount could be a vital factor [26]. It is plausible that the band structure of TiO$_{2-x}$N$_x$ with the lower values of $x < 0.05$ should differ from the higher values of $x > 0.12$.

3.3. Photocatalytic Activity. To explore the photocatalytic activities of the as-prepared samples, the degradation of 4-CP was investigated in both UV and Vis irradiation. 4-CP does not absorb in the Vis region, and therefore the presence of indirect semiconductor photocatalysis can be excluded [19].

Figure 6(a) shows the changes of 4-CP concentration as a function of time in the presence of TiO$_{2-x}$N$_x$ powders under UV irradiation. The undoped TiO$_2$ exhibited the highest activity for 4-CP decomposition. 59% loss of 4-CP in concentration was observed in the presence of P-25
for 120-minute irradiation. The photocatalytic activity of TiO$_2$-xN$_x$ greatly depended on the concentration of N doping. It is obvious that the photocatalytic activity of TiO$_2$-xN$_x$ decreased as x value increase. 19, 31, 41, and 49% 4-CP were photodegraded in the presence of the sample x = 0.041, 0.035, 0.029, and 0.021 for 120 min, respectively. Almost no degradation occurred in the case of the sample x = 0.049. It is important to keep or improve UV photoactivity of TiO$_2$ when it is functionalized for Vis-light-driven catalysis because the most desired solar light source contains about 5% UV and the efficiency of UV utilization for a TiO$_2$-based photocatalyst is much higher for UV than for Vis light [24]. In the present work, the N doping plays a passive role on the UV activity of TiO$_2$.

Similar experiments were conducted under Vis-light irradiation, as shown in Figure 6(b). Irradiating the undoped TiO$_2$ (x = 0) with Vis light did not generate the decrease of 4-CP in concentration, as TiO$_2$ is not Vis-light sensitive. The degradation of 4-CP, however, was observed from all the doped samples, suggesting that N-doping for TiO$_2$ is an effective and feasible approach for achieving Vis-light-driven photocatalysis. As the x value increased, the photocatalytic activity of the sample decreased, which is similar with the case of UV irradiation.

Many factors, for example, surface area, crystallinity, surface hydroxyl density, and oxygen vacancies, affect the activity of a photocatalyst. The activity of a photocatalyst is a combined effect of many factors [24]. In our case, the N-doping concentration dominated these factors because other preparation conditions were identical. Therefore, it is easy to understand that the N-doping concentration in the catalyst could be responsible for the difference of the photocatalytic activity. Irrespective of UV or Vis case, the photoactivities of the N-doped samples decrease with the increase of the N-doping concentration. This is ascribed to the double-faced behaviors of the doped N atoms. The UV-Vis spectra in Figure 3 indicated that the N-doping improved the Vis absorption and increased the number of photons taking part in the photocatalytic reaction. Undoubtedly, this could enhance the photocatalytic activity. On the other hand, they also act as a recombination center of photogenerated charge carriers, and thus deteriorate photocatalysis [26]. The passive role of the N-doped atoms as a recombination center is primary. This was inferred from our results showing a much higher photocatalytic activity is corresponding to the lower x value.

3.4. Formation of Radicals. To probe the nature of the reactive oxygen species generated during the irradiation of the present system, the photodegradation of 4-CP by TiO$_2$-xN$_x$ in the presence of isopropanol under visible irradiation was performed. The results are shown in Figure 7. It was found that addition of isopropanol, a known scavenger of •OH radicals, prohibited greatly the degradation of 4-CP, indicated that the free •OH radicals were involved in this photochemical system. The direct evidence of the reactive oxygen species possibly involved in the photodegradation process was examined by EPR technique (DMPO), as shown in the inset of Figure 7. No ESR signals were observed either when 4-CP was absent or when the reaction was performed in the dark in the presence of the catalysts. Under Vis irradiation the characteristic quartet peaks of DMPO-•OH adduct with 1 : 2 : 2 : 1 in the intensity were observed after a 80-second irradiation, which are consistent with the similar spectra reported by others for the •OH adduct [35].

Although the formation of the superoxide radical anion was expected owing to the scavenging of the electrons by O$_2$, because the N doping did not affect the conduction band of TiO$_2$ [17], the spin-adduct DMPO-•OOH/O$_2$• was not
detected in the aqueous system. It is well documented that the superoxide radical anions are produced first and remain stable in an organic solvent medium (at least in methanol) [36]. When the fraction of H$_2$O is increased, such as occurs in a CH$_3$OH/H$_2$O mixed solvent system, the superoxide radical anion tends to be unstable, especially in H$_2$O alone. It is probably because the facile disproportionation reaction of superoxide in water precludes the slow reactions between $\cdot$OOH/O$_2$$^•_-$ and DMPO ($k = 10$ and $6.6 \times 10^5$M$^{-1}$s$^{-1}$, resp.) [37]. Consequently, we recorded the ESR spectra of the DMPO-$\cdot$OOH/O$_2$$^•_-$ spin adducts in methanolic media, and the results were as shown in the inset of Figure 8. The six characteristic peaks of $\cdot$OOH/O$_2$$^•_-$ adducts were observed under Vis irradiation, and the signal intensity increased slightly with irradiation time. No such signals were observed in the dark; that is, generation of O$_2$$^•_-$ anions in the N-doped TiO$_2$ system inherently implicates irradiation. The effect of superoxide dismutase (SOD) on the 4-CP degradation rate was also observed. The results are shown in Figure 8. The presence of SOD (ca. 10000 units), which catalyzes the dismutation of O$_2$$^•_-$, led to a marked suppression of 4-CP photodegradation. This was in good agreement with the ESR measurement. Kinetics studies by ESR measurements and the radical scavenger techniques clarify that the degradation of visible-light-induced degradation of 4-CP over N-doped TiO$_2$ is derived mainly by the radical reaction, which is similar to that of TiO$_2$ under UV light irradiation.

3.5. Proposed Degradation Pathway. During the photocatalytic degradation, the aromatic intermediates were detected by HPLC. The three intermediates generated during the 4-CP degradation are hydroquinone (HQ), hydroxyhydroquinone (HHQ), and benzoquinone (BQ). Figure 9 illustrates the profiles of the intermediated products during the 4-CP degradation using N-doped TiO$_2$ under Vis-light irradiation.

The initial step is the formation of electron hole pairs on the surface of the catalysts when irradiated by the visible light. The photoinduced electrons at the catalyst surface are scavenged by the ubiquitously present molecular oxygen to yield first O$_2$$^•_-$, whence on protonation yields the HO$_2$ radicals, and to further produce OH whereas the generated holes can react with hydrated surface of the catalyst, resulting in the formation of surface-bound OH directly. Thus the activated oxygen species, OH, O$_2$$^•_-$, and HO$_2$ radicals were involved in this photochemical process. However, it is believable that surface-bound and solvated OH radicals are a main oxidant to attack 4-CP. 4-CP is first oxidized into HQ, and then HQ is further oxidized into HHQ and the opening of the ring, and finally the complete mineralization to H$_2$O and CO$_2$.

4. Conclusions

TiO$_{2-x}N_x$ (0.021 < $x$ < 0.049) has prepared by annealing under an NH$_3$ flow at 550°C. XRD and XPS confirmed that the so-prepared samples had nitrogen substituted at some of the oxygen sites in TiO$_2$. The Ndoping did not cause the red shift of the absorbed edge of TiO$_2$ and revealed that the new absorption shoulder at 400~475 nm, suggesting that an isolated narrow band formed above the valence band could be responsible for the Vis light response of the oxynitride powders. The samples showed the photoactivities for the decomposition of 4-CP under both UV and Vis irradiation. When irradiating with UV or Vis light, the activity of the sample decreased with the increase of the N-doping concentration. ESR measurements gave the clear experimental evidence that the active species, such as $\cdot$OH and O$_2$$^•_-$, generated and participate in the photodegradation of 4-CP over the N-doped TiO$_2$ catalyst.
