Systemic sclerosis (SSc) is a chronic autoimmune disorder characterized by progressive fibrosis of the skin and visceral tissues as well as a non-inflammatory vasculopathy. Vascular disease in systemic sclerosis is a major cause of morbidity and mortality among non-pregnant patients with SSc and is even a bigger concern in the pregnant SSc patient, as the underlying vasculopathy may prevent the required hemodynamic changes necessary to support a growing pregnancy. Vascular manifestations including scleroderma renal crisis and pulmonary arterial hypertension should be considered relative contraindications against pregnancy due to the high associations of both maternal and fetal morbidity and mortality. In contrast, Raynaud’s phenomenon may actually improve somewhat during pregnancy. Women with SSc who are considering a pregnancy or discover they are pregnant require evaluation for the presence and extent of underlying vasculopathy. In the absence of significant visceral vasculopathy, most women with SSc can expect to have reasonable pregnancy outcomes.

1. **Introduction**

Systemic sclerosis (SSc) is a chronic autoimmune disorder characterized by progressive fibrosis of the skin and visceral tissues as well as a non-inflammatory vasculopathy manifesting as Raynaud’s phenomenon, digital ulcerations, pulmonary arterial hypertension, and scleroderma renal crisis. Vascular disease in systemic sclerosis is a major cause of morbidity and mortality among non-pregnant patients with SSc and is even a bigger concern in the pregnant SSc patient, as the underlying vasculopathy may prevent the required hemodynamic changes necessary to support a growing pregnancy. Vascular manifestations including scleroderma renal crisis and pulmonary arterial hypertension should be considered relative contraindications against pregnancy due to the high associations of both maternal and fetal morbidity and mortality. In contrast, Raynaud’s phenomenon may actually improve somewhat during pregnancy. Women with SSc who are considering a pregnancy or discover they are pregnant require evaluation for the presence and extent of underlying vasculopathy. In the absence of significant visceral vasculopathy, most women with SSc can expect to have reasonable pregnancy outcomes.

Akin to many autoimmune diseases, SSc has a strong female predominance, with an approximate female- to male-ratio of 5:1 [1, 2]. SSc is a relatively rare disease, with a prevalence in North America estimated to be approximately 49,000–55,000, between 25 and 44 per 100,000 persons [1, 2]. Symptom onset of SSc usually begins in the 5th decade, approximately 10 years prior to the mean age of menopause. In more recent decades, many women have postponed childbearing into their 30s and 40s for career and other personal reasons. For this reason, the number of women who develop SSc and have not yet completed their families and may be considering pregnancy is likely to increase. When counseling women with SSc who are considering pregnancy or who discover a pregnancy, it is critical to understand the potential vascular complications that may lead to adverse pregnancy outcomes.

2. **Normal Hemodynamic and Vascular Changes of Pregnancy**

In order to accommodate the enlarging uterus and growing fetus, a pregnant woman’s body must make numerous physiologic hemodynamic changes. Many of these changes involve changes in blood volume, vascular resistance, cardiac output, and oxygen consumption. Most physiologic changes begin early in gestation and peak by the late second trimester of pregnancy. Although not definitive, it has been suggested that an initial fall in systemic vascular resistance leads to the other well-established vascular and hemodynamic changes...
of pregnancies [3]. Activation of the renin-angiotensin-
aldosterone system results in a 7-8 liter increase in total
body fluid during gestation (distributed between maternal
intra- and extracellular spaces, fetus, and amniotic fluid)
[4]. Cardiac output increased by 50% over the course of
pregnancy, with the majority of increase occurring within
the first 8 weeks, followed by a gradual increase until
plateau mid-third trimester [5]. This is mediated by an
increase in both stroke volume early in pregnancy and
heart rate throughout pregnancy. During pregnancy, cardiac
output is preferentially distributed to the uterus, kidneys,
skin, and breast tissue and away from skeletal muscle [6].
The pulmonary system additionally undergoes significant
physiologic changes during pregnancy. Pulmonary vascular
resistance decreases. Basal oxygen consumption increases
by 50 mL/min by term, and alveolar ventilation increases,
lowering PCO2 by about 8 torr.

The exact mechanisms underlying the hemodynamic
changes during pregnancy remain to be completely under-
stood. An increase in prostacyclin in both the fetoplacental
tissues and maternal system plays a clear role in systemic
vasodilation; however, additional mediators are required to
explain the degree of reduction in vascular resistance [3].
Nitric oxide (NO) is likely candidate to play a significant role
in the hemodynamic accommodations during pregnancy.
There appears to be a permanent basal activity of NO in
utero- and fetoplacental vasculature in pregnant women; the
trophoblast may be a significant source of NO production
[3]. NO donors administered to women between 8 and
10 weeks gestation resulted in a further fall of peripheral
resistance [7]. Other studies have demonstrated a deficiency
of NO in pregnancy complications associated with defective
placental perfusion: preeclampsia and intrauterine growth
restriction [3]. In addition to the important roles of prosta-
cyclin and NO in the maintenance of low peripheral vascular
resistance, the maternal vasculature appears to be resistant to
the effects of angiotensin II.

Physiologic hemodynamic changes are an integral part
of human pregnancy. In some cases, changes in vascular
blood flow and decreased vascular resistance may lead to
improvement in manifestations of systemic sclerosis. In other
cases, an intrinsic inability to adapt to the necessary hemo-
dynamic changes in pregnancy, possibly due to underlying
vasculopathy of systemic sclerosis, may contribute to adverse
pregnancy outcomes including hypertensive disorders of
pregnancy and intrauterine growth restriction.

3. Maternal and Fetal Outcomes of
the SSc Pregnancy

Given the prominent vasculopathy associated with SSc,
there is concern for an increased risk of adverse pregnancy
outcomes associated with vascular compromise or inability
to make appropriate hemodynamic adaptations to support
a pregnancy. Indeed, early reports suggested very high rates
of maternal death during pregnancy [8–11]. It is likely
for this reason that women with SSc in past decades had
been strongly advised against pregnancy and often counseled
to terminate pregnancies that have occurred [12]. More
recently, a series of retrospective and prospective studies
have provided more detailed analysis of pregnancy outcomes
and have demonstrated that, for most women with SSc,
pregnancy outcomes are reasonably good [13–18]. Reported
rates of early pregnancy loss of 14%–15% [13, 14] are
somewhat increased from the estimated 10% in the general
population. Late pregnancy losses were few, and generally
occurred in women with severe diffuse SSc [14, 16]. Preterm
delivery rates have ranged from 8% to 40% [13, 14, 16]. The
majority of preterm deliveries were on or after gestational
age 34 [14]. Small for gestational age infants (<10th% tile
for gestational age) [19], ranged from 0% to 50% [2, 14, 16]. Cases of preeclampsia were isolated [14, 16]. It
must be remembered, however, that these studies reflect
the experience of approximately 200 patients followed at
tertiary-care centers over a period of 10 years. A population-
based study of pregnancy outcomes among women with
SSc in the United States that utilized administrative hospital
discharge databases identified 504 SSc women who delivered
between 2004 and 2006 [18]. This study found a 22.9% rate
of hypertensive disorders including preeclampsia, a four-
fold increased odds compared to the general population
(85% CI, 2.4–6.6). Similarly, a nearly four-fold increased
rate of intrauterine growth restriction was found. Overall,
the majority of patients with SSc appear to have reasonable
obstetric outcomes although women with rapidly progressive
diffuse disease may be at higher risk for complications.

4. Scleroderma Renal Crisis

Scleroderma renal crisis, characterized by malignant hyper-
tension, proteinuria, acute renal failure, microangiopathic
changes, and the pathognomonic “onion skin” appearance
of renal arteries on pathology, is one of the most severe
complications of SSc [20]. Affecting 5%–10% of SSc patients,
renal crisis characteristically occurs in patients with rapidly
progressing diffuse skin disease of relatively recent onset.
Prior to the widespread use of angiotensin-converting
enzyme (ACE) inhibitors, renal crisis was one of the leading
causes of mortality. Many of the perinatal deaths reported
among SSc patients involved scleroderma renal crisis [7–10].
Even in more recent series, episodes of renal crisis during
pregnancy were reported. Steen et al. reported two cases of
scleroderma renal crisis in a retrospective study of 86
pregnancies occurring after the diagnosis of SSc [12]. Both
cases occurred abruptly in the third trimester of pregnancy
and resulted in preterm delivery. One woman developed
end-stage renal disease, and the other died from status
epilepticus. In a prospective study of 91 pregnancies, Steen
reported two additional cases of renal crisis [13]. Both
women required hemodialysis after delivery. All of these cases
occurred in women with early, rapidly progressive diffuse
disease. It remains unclear if rates of renal crisis are increased
in pregnant women compared to nonpregnant women with
severe diffuse disease. The severity of scleroderma renal crisis
during pregnancy with very high risks of maternal and
fetal morbidity and mortality and the benefits of treatment
with ACE inhibitors to both mother and fetus if renal
crisis is suspected are highly likely to outweigh the risks of fetotoxicity associated with use [14, 21, 22].

Unfortunately, scleroderma renal crisis can be difficult to distinguish from preeclampsia (abrupt onset hypertension and proteinuria) in the pregnant SSc patient; both conditions carry a high risk of severe maternal and fetal complications if not treated aggressively. In situations where the woman has a history of renal crisis or is at high risk for developing renal crisis (early rapidly progressive renal disease), an immediate trial of ACE inhibitors may be indicated. In cases of profound maternal or fetal distress, emergent delivery may be the most appropriate option followed by initiation of ACE inhibitor therapy. In this situation, the definitive therapy for preeclampsia has been completed (delivery), and ACE inhibitors can be instituted without concern of risk of fetotoxicity of antenatal ACE inhibitor exposure [21]. Renal biopsy may be indicated in cases where the distinction between renal crisis and preeclampsia is necessary for management [23].

5. Pulmonary Arterial Hypertension

Pulmonary arterial hypertension (PAH) has been increasingly recognized as a major cause of morbidity and mortality in the SSc population. Estimates of PAH in the SSc population range from 7.85% to 26.7% [24, 25]. In contrast to scleroderma renal crisis, PAH can occur with both limited and diffuse cutaneous disease and may be more prevalent in patients with limited cutaneous disease. PAH in SSc is a result of long standing vasculopathy involving the pulmonary arterial vasculature. Pulmonary arterioles exhibit the same “onion skin” appearance as seen in renal crisis. Symptom onset is often insidious, delaying diagnosis and the introduction of appropriate therapy. Experts recommend routine screening for PAH to ensure early diagnosis and therapy in hopes of preventing remodeling and permanent occlusion of the vessel lumen.

It is clear that women with PAH are at extremely high risk for severe hemodynamic complications during pregnancy as there is significantly less reserve in the pulmonary arterioles to reduce vascular resistance to accommodate the increased blood volume and cardiac output that occurs during pregnancy. Reports estimate a 36%–50% maternal death rate in women with PAH, with the most vulnerable period occurring with delivery and the first two weeks postpartum [26, 27]. A more recent study suggested a slightly lower maternal death rate of 17%–33%, but this is arguably still unacceptably high [28]. Death is usually due to acute cardiovascular collapse. Rates of preterm delivery with resultant neonatal morbidity and mortality are similarly high in the PAH population. For all of these reasons, women with known PAH should be strongly discouraged from becoming pregnant; additionally, women with SSc (diffuse or limited cutaneous disease) should undergo careful screening for subclinical PAH when considering a future pregnancy. Noninvasive evaluation for PAH includes an echocardiogram looking for a pulmonary arterial pressure of >30 mm Hg at rest or an isolated reduced diffusion capacity (DLCO) in the absence of restrictive lung disease on standard pulmonary function testing [24, 25]. Furthermore, all complaints of dyspnea in pregnant SSc patients should prompt an immediate evaluation for development or worsening of PAH. Assessing diffusion capacity using carbon monoxide is considered safe during pregnancy [29].

If a woman with PAH discovers a pregnancy and wishes to continue with the pregnancy or if PAH is diagnosed during an established pregnancy, careful hemodynamic monitoring and comanagement with pulmonologists experienced with PAH is essential. Case reports have described successful use of epoprostenol and sildenafil during pregnancy [24, 26–28, 30–32]. Anticoagulation with low-molecular-weight heparin is recommended to reduce risk of thromboembolism [26], and some have suggested use of supplemental oxygen to maintain a PO2 greater than 70 mm Hg [26]. Inhaled NO has been used in extreme circumstances during labor and delivery [26, 27].

Delivery is a period of extremely high risk in the woman with PAH. Acute hemodynamic changes including increase in cardiac output of 25%–50% during the second stage of labor through delivery with the return of blood volume from the uterus to the main circulation [26, 27]. Increased maternal mortality has been described with general anesthesia [28]. The preferred mode of delivery remains controversial: vaginal delivery is associated with less shifts in blood volume but has a prolonged second stage of labor and issues regarding increased pressure with contractions. Cesarean delivery reduces the second stage of labor and may be necessary in cases of extreme maternal or fetal distress but increases risks of infection and thrombosis [28].

6. Raynauds Phenomenon and Digital Ulceration

Of all vascular complications of SSc, Raynauds phenomenon and digital ulcers are most likely to improve during pregnancy. Raynauds phenomenon is characterized by vascular hyperreactivity and vasospasm. However, when digital vasculopathy becomes more fixed, as is often the case in SSc, chronic poor perfusion leads to digital ulceration. Raynauds phenomenon tends to improve during pregnancy, only to worsen postpartum [15]. Less is known about the development of or healing of digital ulcerations. Improvements may be because the increased blood volume and reduced systemic vascular resistance may improve peripheral circulation. Return to pre-pregnancy hemodynamics leads to return of baseline peripheral circulatory complications. A study of pregnancy outcomes among women with primary Raynauds phenomenon (without SSc or other connective tissue diseases) found a slightly increased risk of preterm delivery and smaller weights among full-term infants [33] but concluded that these outcomes did not have any adverse clinical significance for mother or infant. The study did not evaluate the course of Raynauds phenomenon during the pregnancy or postpartum period.
7. Decidual/Placental Vasculopathy

Given the diffuse vasculopathy present in patients with SSc, there are concerns that the same pathophysiologic changes may occur in the placental vasculature. The higher rates of prematurity and small for gestation age babies seen in SSc pregnancies may be a direct result of placental vascular insufficiency. Most studies did not examine placental tissue, thus not allowing for direct correlation between placental vascular abnormalities and adverse pregnancy outcomes. Histopathologic examination of placentas from a limited number of SSc pregnancies has been reported; all of which reported normal placenta weight for gestational age [34–36]. In one study of three placentas from SSc patients (gestational age at delivery between 34 and 38 weeks) found evidence of decidual vasculopathy with stromal fibrosis and infarcts in chronic villi despite an absence of reported adverse pregnancy outcomes [33]. In another case of a pregnancy SSc patient with intrauterine growth restriction was found to have increased resistance in the umbilical artery by dopper examination at 31-week gestational age. Examination of the placenta after delivery at 37 weeks found numerous placental infarcts, placental mesenchymal dysplasia, decreased vascularity, and stromal fibrosis all consistent with decidual vasculopathy [35]. In the largest study to date, 13 placentas from SSc patients were examined and correlated with perinatal outcomes [36]. Five of 13 placentas demonstrated marked decidual vasculopathy, four of which were associated with intrauterine fetal demise between weeks 16 and 30. Chorioamnionitis and accelerated placental maturation complicated the majority of other placentas. These findings are similar to what is seen in pregnancies complicated by pregnancy-induced hypertension. Indeed, in a nationwide study of pregnancy outcomes of SSc patients, 23% carried a diagnosis of pregnancy-induced hypertension [18]. Thus, placental abnormalities may be present in SSc pregnancies, even in the absence of clinical perinatal complications, and these abnormalities may be more severe correlating with perinatal growth restriction and death.

8. Conclusion

Healthy pregnancies require extensive pulmonary, cardiovascular, and vascular changes to support the fetus during development. An inability to accommodate such changes due to preexisting pulmonary, cardiac, or vascular disease may lead to pregnancy complications and an inability to support the continuance of the pregnancy. Vasculopathy is a prominent feature of SSc in general and may play an important role in adverse pregnancy outcomes in women with preexisting disease. Women with SSc who are contemplating pregnancy or who discover an inadvertent pregnancy should undergo a thorough evaluation for systemic and organ-specific vasculopathy. Those with a history of scleroderma renal crisis or pulmonary arterial hypertension (or patients at high risk for developing these complications) are at the highest risk for maternal and fetal death and other highly morbid complications of pregnancy. Those with or at high risk for renal or pulmonary arterial vasculopathy should be strongly advised against becoming pregnant and to consider termination if a pregnancy occurs. If a woman wishes to continue with a pregnancy after appropriate counseling of risks, aggressive monitoring and co-management with experts in renal or pulmonary arterial disease is mandatory. Medications such as ACE inhibitors and prostaglandins, which can carry risks for congenital malformations or fetal toxicity, need to be considered as the benefits to both mother and fetus may outweigh known risks of antenatal exposure. Labor and delivery is a very vulnerable period in these cases, and patients may require extended observation in the hospital following delivery to watch for acute cardiovascular collapse in cases of PAH.

However, if after thorough evaluation, a woman with SSc does not appear to have vasculopathy of the internal organs, pregnancy may be considered. Raynaud’s phenomenon should not be considered a contraindication to pregnancy in the absence of renal disease or PAH. With careful monitoring by high-risk obstetrics, most women without advanced vasculopathy can expect to have reasonable perinatal outcomes although preterm delivery is common. Advances in neonatology have helped improve the short- and long-term outcomes of premature infants.

Whenever possible, placentas and umbilical cords should be subject to histopathologic examination for evidence of decidual vasculopathy and stromal fibrosis. This will hopefully lead to better understanding of the role of placental vasculopathy in adverse pregnancy outcomes and may additionally provide histopathologic clues to systemic or organ-specific vasculopathy in SSc patients.
