Mn₃O₄ nanoparticles were prepared by a simple chemical route using cetyltrimethylammonium bromide (CTAB) as a template agent. Mn₃O₄ nanocrystals present an octahedral shape, and their crystallite size varies between 20 and 80 nm. They were characterized by XRD, SEM, DTA/TG, and IR spectroscopy. XRD studies confirm the presence of a highly crystalline Mn₃O₄ phase. The Rietveld refinement of the X-ray diffraction data confirms that Mn₃O₄ nanoparticles crystallize in the tetragonal system with space group I41/amd. DTA/TG and XRD measurements demonstrate the phase transition toward a spinel structure between 25 and 700°C. The electrical conductivity increases between 80 and 300°C, suggesting a semiconducting behaviour of Mn₃O₄. Both dielectric dispersion (ϵ') and dielectric loss (ϵ'') were investigated from 80 and 300°C in the frequency range of 10 Hz–13 MHz. The dielectric properties showed typical dielectric dispersion based on the Maxwell-Wagner model.

1. Introduction

Metal oxide nanocrystals are widely applied in catalysis, energy storage, magnetic data storage, sensors, and ferrofluids [1–4]. Tetramanganese oxides (Mn₃O₄) are particularly used as main sources of ferrite materials [5] and applied in numerous industrial fields such as magnetic [6], electrochemical [7], and catalysis [8, 9]. The particle size and morphology may be controlled by using various methods including solvothermal/hydrothermal [10, 11], vapor phase growth [12], vacuum calcining precursors [13], thermal decomposition [14], ultrasonic, gamma, and microwave irradiation [15–17], and chemical liquid homogeneous precipitation [18]. Therefore, Mn₃O₄ compounds show distinct shapes including nanoparticles [19], nanorods [20], nanowires [21], and tetragonal particles [22].

The electrical and magnetic properties of numerous nanomaterials are completely different from those of their bulk counterparts. Changes in dielectric properties were attributed to changes in particle size, shape, and boundaries

[23, 24]. The modified dielectric properties were used as capacitors, electronic memories, and optical filters. Materials exhibiting a giant dielectric constant were already reported elsewhere [25–27]. The high dielectric permittivity and the low loss factors over a wide frequency range are always of a great interest [28]. In a previous work, we synthesized Mn₃O₄ nanomaterials with lozenge morphology under hydrothermal treatment [29]. The temperature dependence of the conductivity between 25 and 220°C obeys the Arrhenius law with activation energy of 0.48 eV. However, the present work describes the preparation of Mn₃O₄ nanomaterials with octahedral shape at room temperature by using a precipitation method. The magnetic properties of the Mn₃O₄ nanocrystals are also studied by the electron paramagnetic resonance (EPR) technique. To the best of our knowledge, only a limited number of studies of the dielectric properties of nanostructured Mn₃O₄ were reported [30–32]. The scope of the present work is to study the dielectric properties of nanostructured Mn₃O₄ nanoparticles as a function of the frequency and the temperature.

2. Experimental Procedure

2.1. Sample Preparation. The synthesis of Mn_3O_4 nanoparticles was performed at room temperature, using the precipitation route [18]. 0.22 mol of $\text{MnCl}_2 \cdot 6\text{H}_2\text{O}$ (Aldrich) was added to 0.44 mol of NaOH (Fluka) aqueous solution. Then 1.37 mmol cetyltrimethylammonium bromide (CTAB) (Sigma) was dispersed and homogenized under slowly magnetic stirring during 24 hours. The precipitate was filtered and carefully washed with distilled water for several times. The resulting product was dried in the oven at 80°C for 24 hours.

The formation of Mn_3O_4 compound in the alkaline aqueous solution may be formulated by the following reactions:

Manganese ions are firstly reduced in alkaline media to $\text{Mn}(\text{OH})_2$ and then decomposed into MnO (see (2) and (3)). Finally, MnO is oxidized to Mn_3O_4 by the atmospheric oxygen.

2.2. Characterisation Techniques. X-ray powder diffraction (XRD) measurements were performed using a Panalytical XPERT PRO MPD diffractometer operating with Cu K α radiation ($\lambda = 0.15406 \text{ nm}$). Crystallographic data (lattice parameters, space group) were determined by using the Highscore software. The XRD pattern was analyzed by the Fullprof program [33] based on the Rietveld method [34] in order to calculate the cell parameters.

Infrared (IR) spectra were recorded in the wavenumber range of $4000\text{--}400 \text{ cm}^{-1}$ with a "Nicolet 380 Spectrometer." The samples were dispersed in pure KBr pellets. Thermal analyses were performed by using the "SetaramSetsys 1750" operating from 25 to 800°C at a heating rate of $5^\circ\text{C} \cdot \text{min}^{-1}$ under air atmosphere. Scanning electron microscopy (SEM) images were obtained by a Zeiss Stereoscan 440 instrument. Conductivity measurements were carried out from 80 to 240°C with $5\text{--}20^\circ\text{C}$ steps by checking the complex impedance spectroscopy with a Hewlett Packard 4129A impedance analyzer. The signal frequency ranged from 10 to 13 MHz .

3. Results and Discussion

3.1. Crystal Structure, Size, and Morphology. Figure 1 shows XRD patterns of as-prepared Mn_3O_4 nanoparticles. The diffraction peaks correspond to the tetragonal Mn_3O_4 single phase (JCPDS Card 01-080-0382). The Rietveld refinement procedure was performed for the investigation of the crystalline structure of as-prepared nanocrystallites. Figure 1 presents the experimental and calculated patterns together with the differential one, deduced from the Rietveld refinement. Mn_3O_4 X-ray data were refined in the tetragonal

FIGURE 1: Rietveld refinement of the structure of Mn_3O_4 from XRD data.

system (space group $I4_1/amd$). An excellent agreement between experimental and calculated patterns is obtained ($\chi^2 = 1.04$). The refined cell parameters of Mn_3O_4 structure are $a = 5.7671(1) \text{ \AA}$, $c = 9.4521(1) \text{ \AA}$, and $V = 314.3401(1) \text{ \AA}^3$. The structure was refined according to these parameters: $R_{wp}(\%) = 2.08$, $R_{exp}(\%) = 2.13$, $R_B(\%) = 1.13$, and $R_F(\%) = 1.37$.

The crystallite sizes were calculated from the major (211) diffraction peak using the Debye Scherrer approximation [35] and are about 50 nm . The morphology of Mn_3O_4 nanoparticles is shown in Figure 2. The formation of Mn_3O_4 nanoparticles is confirmed. Aggregated nanoparticles with octahedral shapes are observed, and their diameter varies between 20 and 80 nm . The SEM results of the Mn_3O_4 nanoparticles agree with the XRD data.

3.2. IR Absorption Spectroscopy. The IR absorption spectra of the pure CTAB and Mn_3O_4 nanopowders calcinated at different temperatures for 2 h are shown in Figure 3. The IR spectrum of as-prepared Mn_3O_4 nanoparticles without any thermal treatment displays three significant absorption bands in the range of $400\text{--}650 \text{ cm}^{-1}$ (Figure 3(b)). The vibration frequency located at 629 cm^{-1} is characteristic of Mn–O stretching modes in tetrahedral sites, whereas the vibration frequency located at 510 cm^{-1} corresponds to the distortion vibration of Mn–O in an octahedral environment. The third vibration band, located at 410 cm^{-1} , can be attributed to the vibration of manganese species ($\text{Mn}^{3+}\text{--O}$) in the octahedral site of Mn_3O_4 [36–39]. Moreover, the broad band at 3436 cm^{-1} and the narrow one at 1646 cm^{-1} correspond to the O–H vibrating mode of the adsorbed water. The two intense adsorption bands located at 2920 and 2840 cm^{-1} are assigned to the symmetric and asymmetric stretching modes of the --CH_2 group of the CTAB surfactant bounded to the surface of Mn_3O_4 , respectively. A comparison of the IR spectrum for pure CTAB (Figure 3(a))

FIGURE 2: SEM images of Mn_3O_4 nanoparticles.

and the spectra relative to the Mn_3O_4 nanoparticles (Figures 3(b), 3(c), and 3(d)) shows invariant frequency positions at 2920, 2840 cm^{-1} , suggesting the absence of intermolecular interactions ($\text{C-H}\cdots\text{O}$) between oxygen atoms of Mn_3O_4 nanoparticles and the $-\text{CH}_2$ groups belonging to the CTAB surfactant. The difference between symmetric and asymmetric scissoring vibrations of $(\text{CH}_3)_3\text{-N}^+$ group of the pure CTAB (1482 cm^{-1}) and CTAB capped on the Mn_3O_4 nanoparticles surface (1429 cm^{-1}) reveals that CTAB adsorbed on the nanoparticle surface interacts strongly with oxygen atoms of Mn_3O_4 (Figure 3(b)). The single band located at 960 cm^{-1} on CTAB spectrum (Figure 3(a)) and the narrow one at 955 cm^{-1} (Figure 3(b)) for bounded CTAB may be assigned to the $(\text{C}-\text{N}^+)$ stretching mode. The frequency shift may be caused by the interaction between $(\text{CH}_3)_3\text{-N}^+$ group and the oxidized metal surface [40]. This type of interaction was also observed between the polymer hydroxypropyl cellulose (HPC) used as capping agent and the silver metal surface [41].

During the heat treatment of Mn_3O_4 , the progressive removal of the organic surfactant is well demonstrated by the IR spectra (Figure 3(b)–(f)) recorded at different temperatures. After two hours of thermal treatment at 500°C, vibration bands corresponding to the surfactant molecules were not observed on IR spectra, indicating that

FIGURE 3: IR spectra of Mn_3O_4 nanoparticles calcined at different temperatures.

all organic groups were removed. During the heating process, a clear difference is observed in the IR spectra, in the range 700–400 cm^{-1} , corresponding of the stretching bands of $\text{Mn}-\text{O}$. This change in the position bands between 300 and 700°C can be related to the phase transformation of Mn_3O_4 . This result is in a good agreement with X-ray diffraction data.

3.3. Thermal Analyses. In order to examine the thermal stability of Mn_3O_4 nanoparticles, thermal gravimetric (TG) and differential thermal analyses (DTA) were carried out between 25 and 800°C (Figure 4). In the temperature range of 25–250°C, the weight loss of 9.15% can be related to the release of weakly adsorbed water molecules and to the removal of the organic entities of CTAB surfactant. The broad exothermic peak at about 350°C, associated with the mass gain, is about 0.4% (Figure 4). As confirmed by earlier studies [42–44], this thermal event can be corroborated by the fact that Mn_3O_4 (Mn^{+II} , Mn_2^{+III}) can be transformed into Mn_5O_8 (Mn_2^{+II} , Mn_3^{+IV}) in the temperature range of 300–450°C [45]. The new (Mn_5O_8) phase is formed according to the following reaction:

Mn_5O_8 phase is isostructural with $\text{Cd}_2\text{Mn}_3\text{O}_8$ and crystallizes in the monoclinic system (C2/m) [46]. Mn_5O_8 was

FIGURE 4: TG/DTA curves of Mn_3O_4 nanoparticles.

observed during the decomposition of manganese oxalate [47] as well as in the transformation of hydrohausmannite into anhydrous hausmannite [46, 48]. The oxidation of Mn^{3+} to Mn^{4+} in the temperature range of 300–450°C leads to the crystallization of the Mn_5O_8 phase. After the exothermic peak at 350°C the mass remains relatively constant.

The endothermic event at 575°C, associated with the weight loss of 2.02% (calculated weight loss 1.98%), are related to the consequent release of oxygen due to the reduction of Mn_5O_8 to Mn_2O_3 . The reaction scheme can be written as follows:

The weight loss is still constant at temperature higher than 700°C, indicating the completion of the thermal decomposition of the intermediate phase (Mn_5O_8) and the beginning of the crystallization of Mn_2O_3 as a new phase.

In order to give a plausible interpretation of the thermal phenomena, we also performed an investigation by X-ray diffraction analysis at different calcination temperatures for 2 h. Several samples of Mn_3O_4 nanoparticles were heated in electric oven (under air atmosphere) at different temperatures: 25, 300, 500, and 700°C, and they are immediately submitted to X-ray diffraction measurements (Figure 5). The X-ray diffraction of the product treated at 300°C is similar to that of the bare sample. This means that Mn_3O_4 nanoparticles are stable up to 300°C. In the temperature range of 25–300°C, XRD peaks gradually become sharper and higher, indicating an improved crystallinity. The X-ray diffraction spectrum at 500°C shows some additional peaks (Figure 5(c)). These diffraction peaks cannot be attributed to Mn_2O_3 , and they are distinguishable from those of Mn_3O_4 . They are observed at $2\theta = 21.741, 31.916, 35.400, 39.250, 47.801, \text{ and } 66.190^\circ$ and indexed to $(-201), (020), (-401), (002), (-421), \text{ and } (-223)$ Bragg peaks, respectively. The corresponding phase is identified as Mn_5O_8 (JCPDS card no. 00-039-1218) [44]. It was already established that Mn_5O_8 is stable up to 550°C and transforms to Mn_2O_3 and Mn_3O_4 phases [49]. In the present case, after calcination at 700°C, the XRD spectrum (Figure 5(d)) shows that all diffraction peaks of Mn_5O_8 and Mn_3O_4 phases disappear. In the same

FIGURE 5: XRD patterns of Mn_3O_4 nanoparticles calcined at different temperatures.

way, a new phase Mn_2O_3 appears (JCPDS card no. 00-41-1442) with typical peaks at $2\theta = 19.02, 23.28, 33.07, 35.87, 38.49, 55.44, \text{ and } 65.92^\circ$. These peaks are indexed to $(200), (211), (222), (321), (400), (440), \text{ and } (622)$, respectively.

Paramagnetic properties of Mn_3O_4 nanoparticles calcined at different temperatures (25°C, 300°C, and 500°C) and cooled at room temperature were studied by the EPR technique (Figure 6). The paramagnetic properties were used in order to study the valence state changes of manganese element as a function of the temperature. Figures 6(a) and 6(b) indicate that the spectra mainly consist in one resonance line centered at $g_{\text{ref}} = 2.33$ that characterizes the unique paramagnetic center (Mn^{2+}) at each resonance feature. The broad EPR line seems to be originating from the electrostatic and dipolar interactions between the manganese ions with mixed valence states. Figure 6(c) shows two resonance peaks corresponding to the paramagnetic centers Mn^{2+} and Mn^{4+} , respectively. This indicates the presence of two Mn_5O_8 ($\text{Mn}_2^{+II}, \text{Mn}_3^{+IV}$) and Mn_3O_4 ($\text{Mn}_1^{+II}, \text{Mn}_2^{+III}$) phases around 500°C. Such a result is in good agreement with the XRD and thermal data and confirms the presence of two phases Mn_3O_4 and Mn_5O_8 around 500°C.

3.4. Conductivity Study. The temperature variation of the electrical conductivity between 80 and 300°C is represented in Figure 7 in the form of $\ln(\sigma T)$ versus $10^4/T$. The electrical conductivity increases with increasing temperature. In the temperature range 80–140°C, the electrical conductivity approximately presents an Arrhenius-type behavior with an activation energy of $E_{a1} = 0.11$ eV. Around 140°C, a break in the curve is observed, accompanied by an increase of the activation energy ($E_{a2} = 0.56$ eV). This behaviour may be related to the removal of water molecules, residual ions, and organic surfactant capped on the surface of Mn_3O_4 particles. This probably affects the conductivity mechanism. It was reported elsewhere that the change in the slope does not

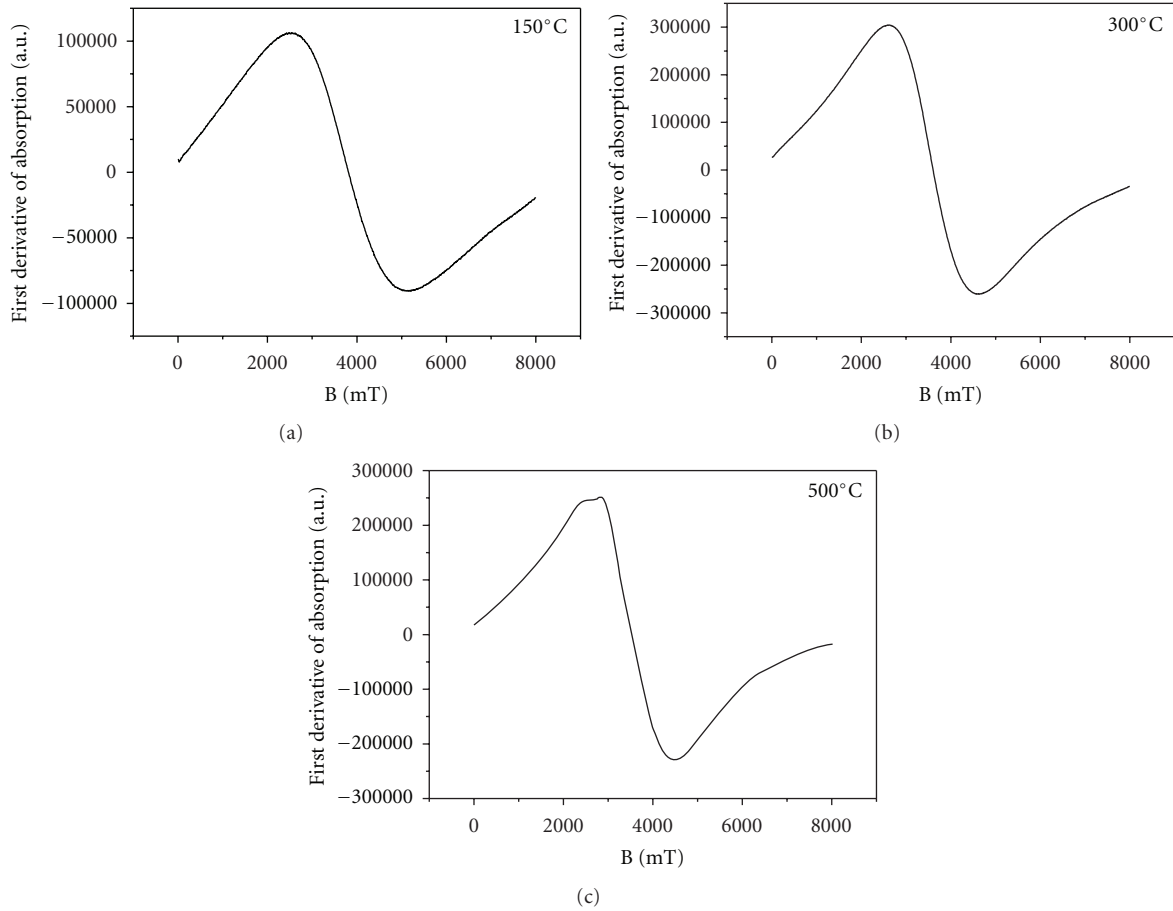

FIGURE 6: EPR spectra of Mn₃O₄ nanoparticles calcined at different temperatures.

FIGURE 7: Arrhenius plot of the electrical conductivity for Mn₃O₄ nanoparticles.

occur for Mn₃O₄ nanoplatelet preliminarily heated at 300°C before being used in the conductivity study [29]. Larson and Arnott have measured the electrical conductivity of Mn₃O₄ bulk materials in the range 0–200°C. The obtained activation energy is 0.75 eV [50].

3.5. Dielectric Analysis. The complex dielectric permittivity is represented by $\epsilon^* = \epsilon' - i\epsilon''$, where ϵ' is the real part of the dielectric permittivity that describes the stored energy, while ϵ'' is the imaginary part of dielectric permittivity related to the dissipation energy (or loss of energy) within the medium [51]. Figure 8(a) shows that the dielectric constant (ϵ') decreases continuously at lower frequencies and remains constant at higher frequencies giving rise to a plateau. The monotonous decrease in the value of dielectric constant on increasing frequency may be attributed to a combined contribution due to electronic, ionic, and interfacial polarization at low frequencies [52]. The observed dielectric dispersion at low frequencies can be explained on the basis of the Maxwell-Wagner theory of interfacial polarization [53]. According to the Maxwell-Wagner model, the dielectric structure of ferrites consists in two layers. The first layer represents a large number of grains that act as conducting layer at higher frequencies and the other layer consists in grain boundaries that act as highly resistive medium at lower frequencies. Similar results were observed for ferrite nanoparticles (Mn_{0.2}Ni_{0.8}Fe₂O₄) [54] as well as in bulk SrNb₂O₆ material [55]. At low frequencies, the polarization process in Mn₃O₄ nanoparticles is explained as a local displacement of electrons by hopping mechanism between Mn²⁺ and Mn³⁺ and an orientation of electric

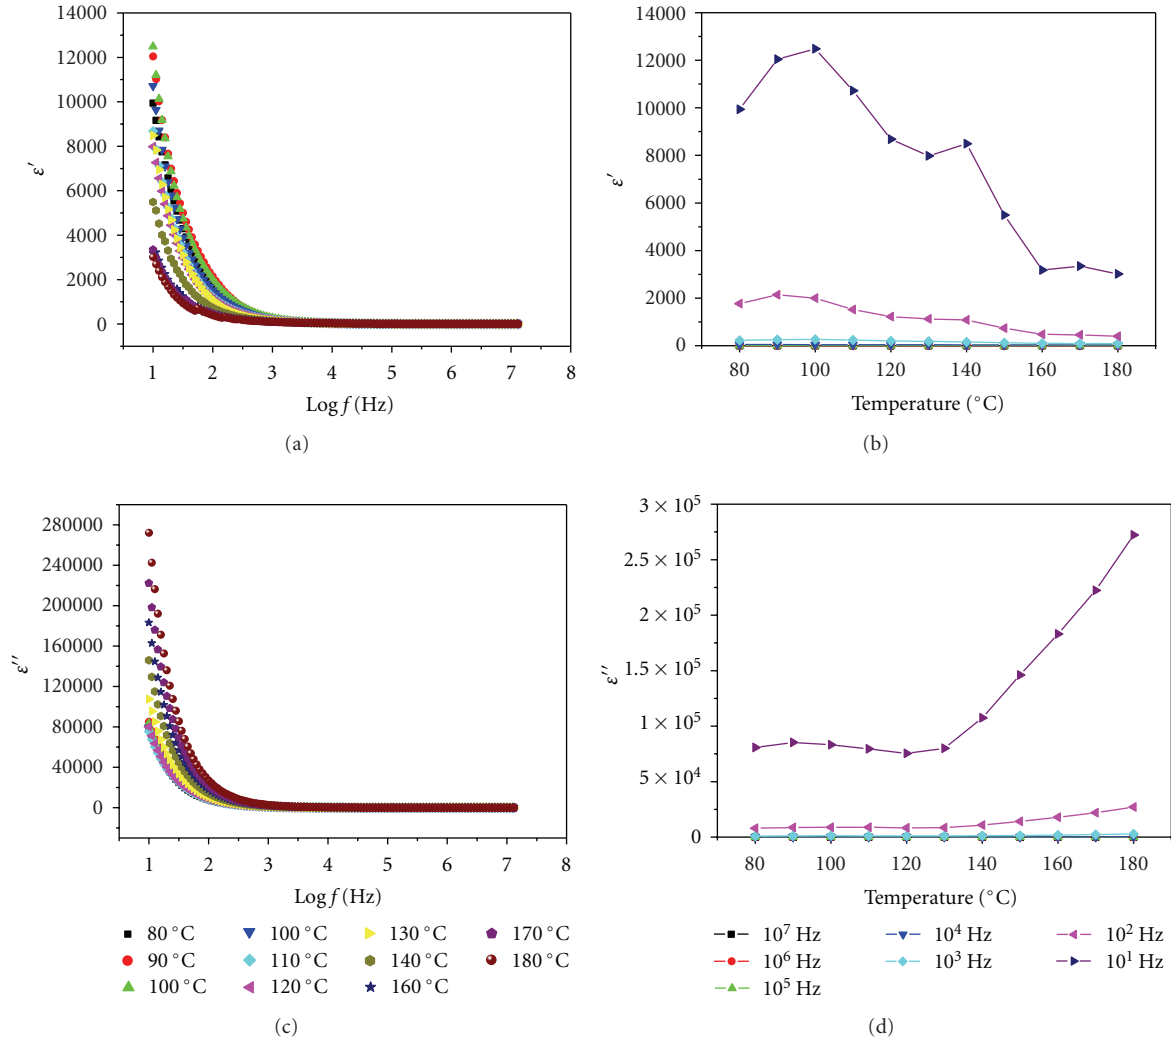

FIGURE 8: (a) Variation of dielectric constant ϵ' versus frequency at different temperatures for Mn_3O_4 nanoparticles. (b) Variation of dielectric constant (ϵ') versus temperature at different frequencies for Mn_3O_4 nanoparticles. (c) Variation of dielectric constant (ϵ'') versus frequency at different temperatures for Mn_3O_4 nanoparticles. (d) Variation of dielectric constant ϵ'' versus temperature at different frequencies for Mn_3O_4 nanoparticles.

dipole in the direction of the applied field. With increasing the frequency, electric dipoles, and the $\text{Mn}^{2+}/\text{Mn}^{3+}$ electron transfer, the net displacement of charge in one direction decreases and then the dielectric constant decreases. The high dielectric values of the Mn_3O_4 nanoparticles are observed for other compounds such as ZnO nanotubes [56] and $\text{Mn}_{0.2}\text{Ni}_{0.8}\text{Fe}_2\text{O}_4$ nanoparticles [54] and for the bulk Mn-Mg spinel ferrite [57]. The large value of dielectric constant is due to the fact that Mn_3O_4 acts as a nanodipole under electric fields. The small-size particles involve large number of particles per unit volume resulting in an increase of the dipole moment per unit volume and the high dielectric constant.

The temperature dependence of dielectric permittivity (ϵ') at selected frequencies is represented in Figure 8(b). The dielectric permittivity increases gradually with the temperature until reaching a maximum value of T_{max} . On the other hand, relaxor ferroelectrics show a broad

peak for the permittivity variation with the temperature at large frequency dispersion [58]. In the present case, a broad peak was observed in the temperature range of 90–120 $^{\circ}\text{C}$ at low frequencies (Figure 8(b)). Other compounds show relaxor dielectric response such as CrTiNbO_6 [59] and FeTiNbO_6 [59]. The relatively insignificant variation of dielectric permittivity with the temperature observed at higher frequencies is attributed to atomic and electronic polarizations.

The imaginary part of the dielectric permittivity ϵ'' shows higher values that decrease rapidly with the frequency and increase as the temperature rises (Figure 8(c)). For nanometer-sized particles, the contribution of the interfacial loss and the loss from electrical conductivity is dominant at lower frequencies, but at high frequencies these losses are negligible. This may explain the decrease in dielectric constant (ϵ'') observed at high frequencies. The large value of the dielectric constant ϵ'' at lower frequency is due to the

predominance of Mn^{2+} ions, oxygen vacancies, and grain boundary defects [60, 61]. Figure 8(d) indicates that the imaginary part ϵ'' is fluctuating and increasing as a function of the temperature at higher frequencies. This suggests that the temperature dependency of the imaginary part is strongly dependent on the frequency range.

4. Conclusion

Mn_3O_4 nanoparticles were successfully prepared by using the precipitation method at room temperature in the presence of CTAB, as a template agent. X-ray structural analyses confirmed that Mn_3O_4 nanoparticles crystallize in the tetragonal system. From XRD and SEM results, Mn_3O_4 nanoparticles exhibit a crystallite size between 20 and 80 nm. XRD and DTA/TG analyses show the apparition of the metastable Mn_5O_8 phase at about 350°C. The paramagnetic properties of Mn_3O_4 samples were studied by the EPR technique in order to study the valence state changes with the temperature and to confirm the presence of the metastable Mn_5O_8 phase around 350°C. Dielectric measurement results show that ϵ' and ϵ'' decrease as the frequency increases. The dielectric dispersion ϵ' and the dielectric absorption ϵ'' of Mn_3O_4 nanoparticles are found to be slightly temperature dependent at higher frequency. These results indicate that the dielectric properties showed a usual dielectric dispersion explained on the basis of the Maxwell-Wagner model.
