We propose two variants of a stochastic epidemic model in which the disease is spread by mobile particles performing random walks on the complete graph. For the first model, we study the effect on the epidemic size of an immunization mechanism that depends on the activity of the disease. In the second model, the transmission agents can gain lives at random during their existences. We prove limit theorems for the final outcome of these processes. The epidemic model with mutations exhibits phase transition, meaning that if the mutation parameter is sufficiently large, then asymptotically all the individuals in the population are infected.

1. Introduction

One of the most important applications of stochastic processes is in epidemiology, more specifically, in studying the spread of epidemics and analyzing mechanisms to control them. The first studies of stochastic systems of epidemics go back to a pioneer paper of McKendrick [1] and the unpublished lecture notes of Reed and Frost, written around 1930. But only since the late 1940s, with Bartlett [2], that stochastic epidemic models began to be studied more extensively. Recently, the mathematical theory of epidemics has experienced a renewal impulse, due to the extension of the concept of a disease, to include computer malware, rumour spreading, and viral marketing. For well-crafted presentations of this theory, the reader should refer to the books by Anderson and May [3], Andersson and Britton [4], Bailey [5], Daley and Gani [6], and Draief and Massoulié [7].

In many models of the literature on epidemics, individuals reside at the vertices of a graph and the disease is transmitted through contacts along the edges, in such a way that the state of an individual depends on the state of other individuals in its vicinity. Typically, one considers the complete graph (representing a homogeneously mixing population) and the dissemination of the disease is described by a continuous-time Markov process whose transition probabilities are nonlinear in nature. The classical approach for studying such stochastic epidemic processes is to analyze the forward equation, which frequently results in differential equations that are very hard to tract analytically. In the last decades, the main advances have been made by using other tools, such as the analysis of the embedded Markov chain, coupling, martingale arguments, and diffusion approximations. In our paper, we study the final outcome of two epidemic processes described through interacting particle systems. Although our models have the standard assumption of homogeneous mixing, the possible interactions are dynamic: we suppose that the viruses are mobile particles which move along the vertices of the graph. In addition, the classical coupling techniques are difficult to apply, by virtue of the dependence between the progeny and the lifetime of the pathogenic agents. Thus, we illustrate how the machinery of density dependent population processes is useful for proving results about the final outcome of stochastic epidemic models on homogeneously mixing populations. This theory, described in Ethier and Kurtz [8, Chapter 11], is also exploited for this purpose in Ball and Britton [9, 10] and Kurtz et al. [11]. A detailed treatment of classical epidemic models on general networks can be found in Draief and Massoulié [7, Chapter 8].

Let us describe the dynamics of the interacting particle system formulated in Kurtz et al. [11], which models the propagation of a disease in a population and the spreading of a virus in a computer network. For $n \geq 3$, let $\mathcal{H}_n$ be
the complete graph on \( n \) vertices, that is, the undirected graph with \( n \) vertices where each pair of vertices is connected by an edge. At time zero, there is one particle at each vertex of \( \mathcal{K}_n \); one of them is active; the others are inactive. Active particles perform independent, continuous-time, rate 1, random walks on \( \mathcal{K}_n \) and, whenever any active particle visits an inactive one, the latter becomes active and starts its own random walk. However each active particle dies at the instant it jumps on a vertex that has already been visited by the process.

To understand the epidemic interpretation, think that the active particles are viruses which move along the vertices of the graph (individuals or computers). During its life, at the time points of a homogeneous Poisson process with intensity 1, a virus moves to a randomly chosen vertex of the graph, different from the one at which it is located. When the virus jumps onto a susceptible individual (i.e., a vertex that has not already been visited by the process), this individual catches the disease and the virus duplicates. Once that happens, the individual is regarded as immunized; that is, it activates an antivirus which will kill any virus that tries to infect it in the future. Thus, we may think that each newly born virus starts with one life, and it dies whenever it jumps onto an immunized individual. Since the process eventually finishes (when all viruses die), the main question concerns the proportion of individuals who ultimately become infected (i.e., the proportion of visited vertices at the end of the process). Kurtz et al. [11] prove a Law of Large Numbers for this proportion, which states that, for large \( n \), approximately 80% of the individuals are infected with high probability. A Central Limit Theorem describing the magnitude of the random fluctuations around this limiting value is also established.

Our purpose is to generalize these limit theorems for two variants of this epidemic model in which we introduce mechanisms of vaccination and mutations of the viruses. In the first model, presented in Section 2, we incorporate a process of vaccination in the epidemic model that depends on the activity of the disease and analyze how this affects the asymptotic distribution of the final epidemic size. In particular, we are able to evaluate the immunization rate required to keep the epidemic at a reasonable level with high probability. In the second model, described in Section 3, we consider a mutation parameter \( \gamma \), which determines the epochs when the viruses gain more lives. This model exhibits a phase transition in the parameter, which means that for \( \gamma < 1 \) asymptotically the infection is restricted to a fraction less than 1 of the population, whereas for \( \gamma \geq 1 \) asymptotically all the individuals are infected. In Section 4, we present some numerical illustrations of the main results for both models. Section 5 is devoted to the proofs.

2. Epidemic Model with Immunization

Let us first review the basic definitions and main results stated for the epidemic model formulated by Kurtz et al. [11]. For each \( n \geq 3 \) and \( t \geq 0 \), let \( V^{(n)}(t) \) and \( A^{(n)}(t) \) denote, respectively, the number of visited vertices and the number of active particles at time \( t \), where \( V^{(n)}(0) = A^{(n)}(0) = 1 \). Then, the evolution of the epidemic is described by a continuous-time Markov chain in \( \mathbb{Z}^2 \) which proceeds according to the following transition scheme:

\[
\begin{align*}
(V^{(n)}(t), A^{(n)}(t)) & \to (V^{(n)}(t) + 1, A^{(n)}(t) + 1) \\
\text{at rate } A^{(n)}(t) \left( \frac{n - V^{(n)}(t)}{n - 1} \right), \\
(V^{(n)}(t), A^{(n)}(t)) & \to (V^{(n)}(t), A^{(n)}(t) - 1) \\
\text{at rate } A^{(n)}(t) \left( \frac{V^{(n)}(t) - 1}{n - 1} \right).
\end{align*}
\]  

The two possible transitions \((1,1)\) and \((0,-1)\) correspond, respectively, to the occurrence of a contagion (infection of a susceptible individual and creation of a new virus) and the occurrence of a removal (death of a virus). The transition rates have the usual meaning; for instance, the first one means that

\[
P(V^{(n)}(t + dt) = i + 1, A^{(n)}(t + dt) = j + 1 | V^{(n)}(t) = i, A^{(n)}(t) = j) = j \left( \frac{n - i}{n - 1} \right) dt + o(dt).
\]

Let

\[
\gamma^{(n)} = \inf \{ t \geq 0 : A^{(n)}(t) = 0 \}
\]

be the time until the epidemic ceases. Notice that if all individuals are infected then the process evolves like a death chain in the second coordinate, so that \( \gamma^{(n)} \) is finite almost surely. Thus, the proportion \( n^{-1} V^{(n)}(\gamma^{(n)}) \) is the final epidemic size (which is called the coverage of \( \mathcal{K}_n \) in Kurtz et al. [11]). To state the limit theorems for this proportion, let \( W_0 \) denote the principal branch of the Lambert \( W \) function. More details on this function may be found in the Appendix. From the results proved in Kurtz et al. [11], we have that

\[
\lim_{n \to \infty} \frac{V^{(n)}(\gamma^{(n)})}{n} = v_\infty \quad \text{in probability},
\]

where

\[
v_\infty = 1 + \frac{1}{2} W_0 \left( -2e^{-2} \right) \approx 0.7968.
\]

Furthermore,

\[
\sqrt{n} \left( \frac{V^{(n)}(\gamma^{(n)})}{n} - v_\infty \right) \xrightarrow{d} N\left(0, \sigma^2\right) \quad \text{as } n \to \infty,
\]

where \( \xrightarrow{d} \) denotes convergence in distribution and \( N(0, \sigma^2) \) is the Gaussian distribution with mean zero and variance given by

\[
\sigma^2 = \frac{v_\infty \left( 1 - v_\infty \right)}{2v_\infty - 1} \approx 0.2727.
\]
This means that, for large \( n \), approximately 80% of the individuals are infected with high probability. In addition, the distribution of the final epidemic size is asymptotically normal with mean 0.7968 and variance 0.2727\( n^{-1} \).

Now we define the first variant of the epidemic model, in which we introduce an infection control mechanism, like an immunization treatment or vaccination. We consider the possibility of immunizing the individuals of the population (vertices of the graph), in order to reduce the epidemic outbreak, and study how this influences the final outcome of the process. We suppose that we cannot kill the active particles (viruses) directly and incorporate a process of immunization of a susceptible individual. The associated occurrence of a contagion, a removal of a virus, and an immunization of a susceptible individual are given, respectively, by

\[
\begin{align*}
V_{\text{co}} &= 1 + \frac{1}{2} W_0 (-2e^{-2}) = 0.7968, \\
\nu_{\text{co}} &= \nu_{\text{co}}(\lambda) = \frac{r_{\text{co}}}{1 + \lambda}, \\
i_{\text{co}} &= i_{\text{co}}(\lambda) = \frac{\lambda r_{\text{co}}}{1 + \lambda}.
\end{align*}
\]

Then,

\[
\lim_{n \to \infty} V_{\text{co}}^{(n)} = V_{\text{co}}, \quad \lim_{n \to \infty} i_{\text{co}}^{(n)} = i_{\text{co}} \quad \text{in probability.}
\]

**Theorem 1.** Define

\[
\begin{align*}
r_{\text{co}} &= 1 + \frac{1}{2} W_0 (-2e^{-2}) = 0.7968, \\
\nu_{\text{co}} &= \nu_{\text{co}}(\lambda) = \frac{r_{\text{co}}}{1 + \lambda}, \\
i_{\text{co}} &= i_{\text{co}}(\lambda) = \frac{\lambda r_{\text{co}}}{1 + \lambda}.
\end{align*}
\]

**Theorem 2.** One has

\[
\sqrt{n} \left( V_{\text{co}}^{(n)} - V_{\text{co}} \right) \overset{\mathcal{D}}{\longrightarrow} N_2(0, \Sigma) \quad \text{as} \ n \to \infty,
\]

where \( N_2(0, \Sigma) \) is the bivariate normal distribution with mean zero and covariance matrix \( \Sigma \) given by

\[
\Sigma_{11} = \frac{r_{\text{co}}(2r_{\text{co}} - 1)(1 - V_{\text{co}}) + 2\nu_{\text{co}}(1 - r_{\text{co}})^2}{(1 + \lambda)(2r_{\text{co}} - 1)^2}, \\
\Sigma_{12} = \frac{i_{\text{co}} \left[ \lambda (1 - r_{\text{co}}) - (2r_{\text{co}} - 1)^2 \right]}{(1 + \lambda)(2r_{\text{co}} - 1)^2}, \\
\Sigma_{22} = \frac{\lambda \left[ r_{\text{co}}(2r_{\text{co}} - 1)(r_{\text{co}} + \nu_{\text{co}} - 1) + 2i_{\text{co}}(1 - r_{\text{co}})^2 \right]}{(1 + \lambda)(2r_{\text{co}} - 1)^2}.
\]

The proofs of Theorems 1 and 2 are given in Section 5. The dependence of the limiting fractions of infected and immunized individuals on \( \lambda \) is illustrated in Figure 1(a). As one would expect, increasing the immunization rate \( \lambda \) pushes the value of \( V_{\text{co}} \) towards zero. This means that the epidemic outbreak can be controlled by a suitable choice of the immunization rate. In Figure 1(b), the components of the covariance matrix \( \Sigma \) are plotted as a function of \( \lambda \).

We underline that the Central Limit Theorem allows us to evaluate the immunization rate required to keep the epidemic at a reasonable level with high probability. Indeed, given a large value of \( n \), and numbers \( \nu_{\text{max}} \in (0, 1) \) and \( \alpha \in (0, 1) \), we can compute the value of \( \lambda \) for which the probability that \( V_{\text{co}}^{(n)} \leq \nu_{\text{max}} \) is approximately equal to \( \alpha \). Table 1 exhibits the required values of \( \lambda \) for some arbitrarily chosen values of \( n \), \( \nu_{\text{max}} \) and \( \alpha \).

### 3. Epidemic Model with Mutations

Now we define a version of the epidemic model with mutations, in which a virus is allowed a random number of jumps to already visited vertices before dying (i.e., it has a random number of lives). In biological terms, this corresponds to the ability of the pathogenic agents to develop resistance, by evolutionary adaptation. We consider the initial configuration with one particle per vertex of \( \mathcal{X}_n \), only one of them being active. We assume that each newly activated
particle starts with one life and assigns to it two independent Poisson clocks, with rates 1 and \( \nu \). Poisson clocks assigned to different particles are independent of each other. The rate \( \nu \) Poisson clock determines the mutation times: every time it rings, the active particle gains one life. As usual, the rate 1 Poisson clock determines the jump epochs of the particle. If the chosen vertex has already been visited, then the active particle loses one life (dying if it has one life); otherwise the inactive particle on this vertex is activated. We call \( \nu \) the mutation rate.

Let \( V^{(n)}(t) \) be the number of visited vertices at time \( t \), and let \( A_i^{(n)}(t) \) be the number of active particles with \( i \) lives at time \( t \) (\( i \geq 1 \)). We also define \( A_i^{(n)}(t) = \sum_{i=1}^{\infty} A_i^{(n)}(t) \) the number of active particles at time \( t \). Notice that the infinite-dimensional process \( \{(V^{(n)}(t), A_1^{(n)}(t), A_2^{(n)}(t), \ldots)\}_{t \geq 0} \) makes transitions in continuous time according to the following transition rates:

<table>
<thead>
<tr>
<th>Transition in ( (t, t + dt) )</th>
<th>Infinitesimal rate</th>
</tr>
</thead>
<tbody>
<tr>
<td>( (1, 1, 0, 0, \ldots) )</td>
<td>( \left( \frac{n - V}{n - 1} \right) A_i )</td>
</tr>
<tr>
<td>( (0, -1, 0, 0, \ldots) )</td>
<td>( \left( \frac{V - 1}{n - 1} \right) A_1 )</td>
</tr>
<tr>
<td>( (0, \ldots, 0, 1, -1, 0, 0, \ldots) )</td>
<td>( \left( \frac{V - 1}{n - 1} \right) A_j ) ( j = 2, 3, \ldots )</td>
</tr>
<tr>
<td>( (0, \ldots, j + 1, j, 0, 0, \ldots) )</td>
<td>( \nu A_j ) ( j = 1, 2, \ldots )</td>
</tr>
<tr>
<td>( (0, \ldots, j + 1, j + 2, 0, 0, \ldots) )</td>
<td></td>
</tr>
</tbody>
</table>

We underline an important feature of this epidemic model: it may continue forever, even if every individual is infected by the disease. We consider the process as finished either when there are no more active particles or when the whole population is infected; that is, we define its absorption time by

\[
y^{(n)} = \inf \{ t \geq 0 : A^{(n)}(t) = 0 \text{ or } V^{(n)}(t) = n \}.
\]

Thus, \( V_F^{(n)} = V^{(n)}(y^{(n)})/n \) is the final epidemic size.

Next we present the limit theorems for the final epidemic size. The Law of Large Numbers states that the epidemic model with mutations exhibits phase transition, in the sense that the limiting value of the final epidemic size is less than 1 or equals 1 accordingly as \( \nu < 1 \) or \( \nu \geq 1 \). That is, if the pathogenic agents are able to gain resistance at a very large rate, then a global outbreak affecting all individuals is almost certain to occur.

**Theorem 3.** (i) For \( \nu < 1 \), one defines

\[
h(\nu) = \frac{2}{1 - \nu},
\]

\[
v_{co} = v_{co}(\nu) = 1 + \frac{1}{h(\nu)} W_0(-h(\nu)e^{-h(\nu)}).
\]

Then,

\[
\lim_{n \to \infty} v_{F}^{(n)} = v_{co} \text{ in probability.}
\]
From (9), we conclude that the continuous-time Markov chain \( \{Z(n)(t)\}_{t \geq 0} \) has the following table of possible density functions of the limiting Gaussian distributions and the corresponding asymptotic bivariate normal density. As can be seen, there is an excellent agreement between the empirical distributions and the theoretical limiting distributions.

We also ran 10000 simulations of the epidemic model with population size \( n = 1000 \) and mutation parameter \( \nu = 0.2 \). For this choice of \( \nu \), the theoretical asymptotic values are \( \nu_{\infty} = 0.8926 \) and \( \sigma^2 = 0.149 \). The corresponding estimates obtained from the simulations were 0.8921 and 0.15. Figure 5 presents the histogram of the rescaled final epidemic size from the simulations, with the limiting normal probability density function superimposed.

5. Proofs

A fundamental approach to study the behaviour of stochastic epidemic processes is to analyze their large population deterministic limits and diffusion approximations. In our proofs, we achieve that by applying the theory of density dependent population processes, described in Ethier and Kurtz [8, Chapter 11]. In particular, we will rely on Theorem 11.4.1 therein, which enables limit theorems to be derived for the final outcome of the epidemic models. To use this result, however, we have to first change the pace at which the process evolves, without affecting where it is absorbed. The main steps follow a path similar to that presented in Kurtz et al. [11].

5.1. Proofs of Theorems 1 and 2. For \( t \geq 0 \), we define

\[
Z^{(n)}(t) = \left( V^{(m+1)}(t) - 1, A^{(m+1)}(t), I^{(m+1)}(t) \right),
\]

and

\[
Z^{(n)}(t) = \left( V^{(n)}(t), A^{(n)}(t), I^{(n)}(t) \right)
\]

where

\[
Z^{(n)}(t) = \frac{Z^{(n)}(t)}{n} = \left( \frac{V^{(n+1)}(t)}{n} - 1, \frac{A^{(n+1)}(t)}{n}, \frac{I^{(n+1)}(t)}{n} \right).
\]

From (9), we conclude that the continuous-time Markov chain \( \{Z^{(n)}(t)\}_{t \geq 0} \) has the following table of possible...
transitions and associated rates, all relating to a time increment \((t, t+dt)\):

Transition in \((t, t+dt)\)  |  Infinitesimal rate  
---|---
\(u_0 = (1, 1, 0)\)  |  \(na(1-i-v)\),  
\(u_1 = (0, -1, 0)\)  |  \(na(i+v)\),  
\(u_2 = (0, 0, 1)\)  |  \(\lambda na \left( \frac{n}{n+1} \right)(1-i-v)\).

Thus, the transition rates depend on the current state of the process only through the density process \(z^{(n)}\), so \([Z^{(n)}(t)]_{t\geq 0}\) is a density dependent population process. Observe that we are dealing with the epidemic model on \(\mathbb{R}_{n+1}\), but the denominator in (22) is equal to \(n\). We adopt this definition only to facilitate the application of the related theory.

Let
\[
\tau^{(n)} = \inf \{ t \geq 0 : a^{(n)}(t) = 0 \} = y^{(n+1)}
\]

denote the absorption time of the process \([Z^{(n)}(t)]_{t\geq 0}\). Since
\[
v_F^{(n+1)} = \frac{nv_F^{(n)}(\tau^{(n)}) + 1}{n+1}, \quad i_F^{(n+1)} = \frac{ni_F^{(n)}(\tau^{(n)})}{n+1}.
\]

Theorems 1 and 2 are established once we prove the following lemmas.

**Lemma 5.** \(\lim_{n\to\infty} v_F^{(n)}(\tau^{(n)}) = \nu_\infty\) and \(\lim_{n\to\infty} i_F^{(n)}(\tau^{(n)}) = i_\infty\) in probability, where \(\nu_\infty\) and \(i_\infty\) are given by (11).

**Lemma 6.** \(\sqrt{n}(v_F^{(n)}(\tau^{(n)}) - \nu_\infty, i_F^{(n)}(\tau^{(n)}) - i_\infty) \xrightarrow{D} N_2(0, \Sigma)\) as \(n \to \infty\), where \(\Sigma\) is given by (14).

To prove these results, the first step is to define a new version of the process \(Z^{(n)}\), for which we can apply Theorem 11.4.1 of Ethier and Kurtz [8].
5.1.1. Time-Changed Process. Consider the discrete-time embedded Markov chain of the process \( Z^{(n)} \), that is, the discrete-time Markovian structure obtained from \( Z^{(n)} \) by ignoring the waiting times between consecutive jumps. It is not difficult to see that the distribution of \( (\tilde{v}^{(n)}(t), i^{(n)}(t)) \) depends on \( Z^{(n)} \) only through this embedded Markov chain. Hence, by defining the waiting times between consecutive transitions suitably, we can construct a coupled process \( \tilde{Z}^{(n)} \) with the same transitions as the original process \( Z^{(n)} \) until absorption, though with time at a different pace. This construction is done in such a way that the process \( \{\tilde{Z}^{(n)}(t)\}_{t\geq0} \) has associated transition rates given by

\[
\begin{align*}
\text{Transition in } (t, t+dt) & \quad \text{Infinitesimal rate} \\
\upsilon_0 &= (1, 1, 0) & n(1 - \tilde{v} - \bar{v}), \\
\upsilon_1 &= (0, -1, 0) & n\bar{v}, \\
\upsilon_2 &= (0, 0, 1) & \lambda n \left( \frac{n}{n+1} \right)(1 - \tilde{v} - \bar{v}),
\end{align*}
\]

where

\[
\tilde{Z}^{(n)}(t) = \frac{\tilde{Z}^{(n)}(0)}{n} = (\tilde{v}^{(n)}(t), i^{(n)}(t), \bar{v}^{(n)}(t)).
\]

Furthermore, defining \( \bar{v}^{(n)} = \inf\{t \geq 0 : \bar{v}^{(n)}(t) = 0\} \), we have that

\[
\begin{align*}
\tilde{v}^{(n)}(t) &= \tilde{v}^{(n)}(\bar{v}^{(n)}), \\
i^{(n)}(t) &= i^{(n)}(\bar{v}^{(n)}).
\end{align*}
\]

Now we define the functions

\[
\begin{align*}
\beta_{\upsilon_0}(v, a, i) &= 1 - (i + v), \\
\beta_{\upsilon_1}(v, a, i) &= i + v, \\
\beta_{\upsilon_2}(v, a, i) &= \lambda \left[ 1 - (i + v) \right],
\end{align*}
\]

so the infinitesimal rates in (26) admit the form \( n[\beta_{\upsilon_n}(\bar{v}, \tilde{v}, i)] + O(1/n) \). Consequently, \( \{\tilde{Z}^{(n)}(t)\}_{t\geq0} \) is a density dependent population process with possible transitions in the set \( \{\upsilon_0, \upsilon_1, \upsilon_2\} \).

5.1.2. Deterministic Limit of the Time-Changed Process. Towards proving Lemmas 5 and 6, we use Theorem 11.2.1 of Ethier and Kurtz [8] to conclude that the time-changed system converges almost surely as \( n \to \infty \) (on a suitable probability space). The corresponding drift function is given by

\[
F(v, a, i) = \sum_{i=0}^{3} u_i \beta_{\upsilon_i}(v, a, i)
\]

hence we obtain the following system of ordinary differential equations for the large population limit deterministic system:

\[
\begin{align*}
v'(t) &= 1 - (i(t) + v(t)), \\
a'(t) &= 1 - 2(i(t) + v(t)), \\
i'(t) &= \lambda \left[ 1 - (i(t) + v(t)) \right],
\end{align*}
\]

To solve this system, we define \( r(t) = i(t) + v(t), t \geq 0 \). From (31), it follows that \( r(t) \) satisfies the ordinary differential equation \( r'(t) = (1 + \lambda)(1 - r(t)) \) with initial condition \( r(0) = 0 \), whence

\[
r(t) = 1 - e^{-(1+\lambda)t}, \quad t \geq 0. \tag{32}
\]

Now we define the function \( f : [0, 1) \to \mathbb{R} \) given by

\[
f(r) = \frac{2r + \log(1 - r)}{1 + \lambda}. \tag{33}
\]

Then, by solving each ordinary differential equation in (31), we obtain that the solution of this system is given by \( x(t) = (v(t), a(t), i(t)) \), where

\[
\begin{align*}
v(t) &= r(t), \\
a(t) &= f(r(t)) = \frac{2r(t)}{1 + \lambda} - t, \tag{34}
\end{align*}
\]

It follows from Theorem 11.2.1 of Ethier and Kurtz [8] that, as \( n \to \infty \), \( \tilde{Z}^{(n)}(t) \) converges almost surely to \( x(t) \), uniformly on any finite time interval. Furthermore, analogously to Lemma 3.6 in Kurtz et al. [11], it can be proved that \( \tilde{v}^{(n)}(t) \) converges almost surely to \( v(t) \), uniformly on \( \mathbb{R} \), and that the same assertion holds for \( \tilde{a}^{(n)} \) and \( i \).

5.1.3. Proofs of Lemmas 5 and 6. Both results follow from Theorem 11.4.1 of Ethier and Kurtz [8] applied to the time-changed process \( \tilde{Z}^{(n)} \) (recall formula (28)). We adopt the notations used there, except for the Gaussian process \( V \) defined on page 458, that we would rather denote by \( \mathcal{U} = (U_v, U_a, U_i) \). Here \( \phi(v, a, i) = a \), and

\[
\tilde{Z}^{(n)} = \inf\{t \geq 0 : \tilde{a}^{(n)}(t) \leq 0\}. \tag{35}
\]

We also observe that \( r_\infty \) given in (11) is the unique root of the function \( f \) in the interval \((0, 1)\) (see the Appendix for more details). In addition, the function \( r(\cdot) \) in (32) establishes a one-to-one correspondence between \((0, \infty)\) and \((0, 1)\). Consequently, defining

\[
\gamma_\infty = \inf\{t \geq 0 : a(t) \leq 0\}, \tag{36}
\]

we conclude from (11) and (34) that \( \gamma_\infty = 2\gamma_\infty \), \( v_\infty = v(\gamma_\infty) \), and \( i_\infty = i(\gamma_\infty) \). Thus, to establish Lemma 5, it is enough to prove that

\[
\lim_{n \to \infty} \tilde{Z}^{(n)} = \gamma_\infty \quad \text{almost surely.} \tag{37}
\]
The latter is exactly the first main statement of the proof of Theorem II.4.1 from Ethier and Kurtz [8], whose argument we recall. The facts that \( a'(0) > 0 \) and
\[
\forall \phi \left( x \left( y_{\infty} \right) \right) \cdot F \left( x \left( y_{\infty} \right) \right) = a' \left( y_{\infty} \right) = 1 - 2 \sigma = 0 \quad (38)
\]
and
\[
\text{imply that } a(y_{\infty} - \varepsilon) > 0 \text{ and } a(y_{\infty} + \varepsilon) < 0 \text{ for } 0 < \varepsilon < y_{\infty}.
\]
Then, the almost sure convergence of \( a_n \) to \( a \) uniformly on any finite time interval yields (37).

With regard to Lemma 6, we obtain from Theorem II.4.1 of Ethier and Kurtz [8] that \( \sqrt{n} \left( \hat{Z}^{(n)}(t) - y^{(n)}(t) \right) = \sigma \cdot \hat{Z}^{(n)}(t) \) converges in distribution as \( n \rightarrow \infty \) to
\[
\left( U_{i} \left( y_{\infty} \right) - \frac{1 - \sigma}{1 - 2 \sigma} U_{i} \left( y_{\infty} \right), U_{i} \left( y_{\infty} \right) - \frac{\lambda \left( 1 - \sigma \right)}{1 - 2 \sigma} U_{i} \left( y_{\infty} \right) \right).
\]

The resulting asymptotic distribution is a mean zero bivariate normal distribution, whose covariance matrix \( \Sigma \) can be computed with the aid of a mathematical software. First, the matrix of partial derivatives of the drift function \( F \) and the matrix \( G \) are obtained as
\[
\partial F \left( v, a, i \right) = \begin{pmatrix} -1 & 0 & -1 \\ -2 & 0 & -2 \\ -\lambda & 0 & -\lambda \end{pmatrix},
\]
\[
G \left( v, a, i \right) = \begin{pmatrix} 1 - (i + v) & 1 - (i + v) & 0 \\ 1 - (i + v) & 1 & 0 \\ 0 & 0 & \lambda \left( 1 - (i + v) \right) \end{pmatrix}.
\]
Furthermore, the solution \( \Phi \) of the matrix equation
\[
\frac{\partial}{\partial t} \Phi \left( t, s \right) = \partial F \left( \nu(t), a(t), i(t) \right) \Phi \left( t, s \right), \quad \Phi \left( s, s \right) = I_3
\]
is given by
\[
\Phi \left( t, s \right) = \frac{1}{1 + \lambda} \begin{pmatrix} e^{(s-t)(1+\lambda)} + \lambda & 0 & e^{(s-t)(1+\lambda)} - 1 \\ 2 \left( e^{(s-t)(1+\lambda)} - 1 \right) & 1 + \lambda & 2 \left( e^{(s-t)(1+\lambda)} - 1 \right) \\ \lambda \left( e^{(s-t)(1+\lambda)} - 1 \right) & 0 & \lambda e^{(s-t)(1+\lambda)} + 1 \end{pmatrix}.
\]

Thus, using that the covariance matrix of the Gaussian process \( U \) is
\[
\text{Cov} \left( U \left( t \right), U \left( r \right) \right) = \int_{0}^{\infty} \Phi \left( t, s \right) G \left( \nu(s), a(s), i(s) \right) \Phi^{T} \left( r, s \right) ds,
\]
we get that
\[
\text{Cov} \left( U \left( y_{\infty} \right), U \left( y_{\infty} \right) \right) = \frac{1}{1 + \lambda} \begin{pmatrix} r_{\infty} \left( 1 - v_{\infty} \right) & i_{\infty} & -i_{\infty} r_{\infty} \\ i_{\infty} & y_{\infty} \left( 2 r_{\infty} + \lambda - 1 \right) & -i_{\infty} \left( 2 r_{\infty} + \lambda - 1 \right) \\ -i_{\infty} r_{\infty} & -i_{\infty} \left( 2 r_{\infty} + \lambda - 1 \right) & \lambda r_{\infty} \left( 1 - i_{\infty} \right) \end{pmatrix}.
\]

Finally, we obtain formula (14) by using the well-known properties of variance and covariance and simplifying properly.

5.2. Proofs of Theorems 3 and 4. For \( t \geq 0 \), we define
\[
Z^{(n)} \left( t \right) = \left( V^{(n+1)} \left( t \right) - 1, A_1^{(n+1)} \left( t \right), A_2^{(n+1)} \left( t \right), \ldots \right),
\]
\[
Z^{(n)} \left( t \right) = \left( \nu(t), a_1(t), a_2(t), \ldots \right).
\]
Thus, using that the covariance matrix of the Gaussian process \( \hat{Z}^{(n)}(t) \) makes transitions in continuous time according to the following transition rates:
\[
\text{Transition in } (t, t + dt) \quad \text{Infinitesimal rate}
\]
\[
\begin{align*}
(1, 1, 0, 0, \ldots) & \quad na \left( 1 - v \right), \\
(0, -1, 0, 0, \ldots) & \quad nva, \\
(0, 0, 1, 0, 0, \ldots) & \quad nva_j \quad j = 2, 3, \ldots, \\
(0, 0, 1, 0, 0, \ldots) & \quad \text{for } j = 1, 2, \ldots.
\end{align*}
\]
Denoting the absorption time of this process by
\[
\tau^{(n)} = \inf \left\{ t \geq 0 : a^{(n)} \left( t \right) = 0 \text{ or } j^{(n)} \left( t \right) = 1 \right\} = y^{(n+1)},
\]
we obtain that
\[
\nu^{(n+1)} = \frac{n y^{(n)} \left( \tau^{(n)} \right) + 1}{n + 1}.
\]

Consequently, Theorems 3 and 4 are established once we prove the following results.

**Lemma 7.** If \( v < 1 \), then \( \lim_{n \rightarrow \infty} \nu^{(n)}(\tau^{(n)}) = v_{\infty} \) in probability, and \( \sqrt{n} \left( \nu^{(n)}(\tau^{(n)}) - y_{\infty} \right) \rightarrow N(0, \sigma^2) \) as \( n \rightarrow \infty \), where \( v_{\infty} \) and \( \sigma^2 \) are given, respectively, by (17) and (21).

**Lemma 8.** If \( v \geq 1 \), then \( \lim_{n \rightarrow \infty} \nu^{(n)}(\tau^{(n)}) = 1 \) in probability.

The main idea to prove Lemma 7 is to define a time-changed version \( \tilde{Z}^{(n)}(t) \) of the process \( Z^{(n)}(t) \) and then apply Theorem II.4.1 of Ethier and Kurtz [8] to a density dependent Markov chain in \( \mathbb{Z}^2 \) obtained from \( \tilde{Z}^{(n)}(t) \). The proof
of Lemma 8 is similar, except for the fact that we work with another time-changed reduced Markov chain. Since the arguments are analogous to those presented in Section 5.1 and in Kurtz et al. [11], we present only the main steps of the proofs.

5.2.1. Proof of Lemma 7. We can define a coupled process $\tilde{Z}^{(n)}(t)$ with the same transitions as the process $Z^{(n)}(t)$ until absorption, though with time at a different pace. In view of (46), the process $\{\tilde{Z}^{(n)}(t)\}_{t\geq 0}$ is constructed in such a way that it has the same possible transitions as $Z^{(n)}(t)$ during each time increment, but the associated rates are given by

\[
\begin{align*}
\text{Transition in } (t, t + dt) & \quad \text{Infinitesimal rate} \\
(1, 1, 0, 0, \ldots) & \quad n(1 - \tilde{v}), \\
(0, -1, 0, 0, \ldots) & \quad n\tilde{a}_1 (\tilde{a})^{-1}, \\
(0, \ldots, 0, 1, \ldots, 0, \ldots) & \quad n\tilde{a}_j (\tilde{a})^{-1} \quad j = 2, 3, \ldots, \\
(0, \ldots, 0, -1, 1, 0, \ldots) & \quad n\tilde{a}_j (\tilde{a})^{-1} \quad j = 1, 2, \ldots,
\end{align*}
\]

(49)

where

\[
\tilde{v}^{(n)}(t) = \frac{\tilde{Z}^{(n)}(t)}{n} = (\tilde{v}^{(n)}(t), \tilde{a}_1^{(n)}(t), \tilde{a}_2^{(n)}(t), \ldots).
\]

(50)

We observe that $\tilde{a}^{(n)}(t) = \sum_{i=1}^{\infty} \tilde{a}_i^{(n)}(t)$ corresponds to $a^{(n)}(t)$ in the new time-scale. Moreover, defining $\mathbf{\tilde{r}}^{(n)}(t) = \inf \{ t \geq 0 : \tilde{a}^{(n)}(t) = 0 \text{ or } \tilde{v}^{(n)}(t) = 1 \}$, we have that $\mathbf{\tilde{r}}^{(n)}(t) = \tilde{v}^{(n)}(\mathbf{\tilde{r}}^{(n)})$.

In order to prove Lemma 7 using Theorem 11.4.1 of Ethier and Kurtz [8], we work with a reduced Markov chain. We define

\[
\tilde{y}^{(n)}(t) = \sum_{i=1}^{\infty} \tilde{a}_i^{(n)}(t),
\]

(51)

and let $\bar{z}^{(n)}(t) = (\tilde{v}^{(n)}(t), \tilde{y}^{(n)}(t), t \geq 0)$. Notice that $\{\bar{z}^{(n)}(t)\}_{t\geq 0}$ is a Markov process that summarizes the evolution of the finite-dimensional process $\{\tilde{Z}^{(n)}(t)\}_{t\geq 0}$. During each time increment $dt$, the possible state transitions associated to $\{\bar{z}^{(n)}(t)\}_{t\geq 0}$ are $u_0 = (1, 1), u_1 = (0, -1),$ and $u_2 = (0, 1)$. In fact, we have that $\{\bar{z}^{(n)}(t)\}_{t\geq 0}$ is a density dependent Markov chain with corresponding transition functions given by

\[
\beta_{u_0}(v, y) = 1 - v, \quad \beta_{u_1}(v, y) = v, \quad \beta_{u_2}(v, y) = y.
\]

(52)

Lemma 7 follows from Theorem 11.4.1 of Ethier and Kurtz [8] applied to $\bar{z}^{(n)}$. Here, we have that

\[
F(v, y) = (1 - v, 1 - 2v + v), \quad \varphi(v, y) = y(1 - v).
\]

(53)

The corresponding system of ordinary differential equations is

\[
\begin{align*}
v'(t) &= 1 - v(t), \\
y'(t) &= 1 - 2v(t) + v, \\
v(0) &= y(0) = 0.
\end{align*}
\]

(54)

To solve this system, we define the function $f : [0, 1) \rightarrow \mathbb{R}$ given by $f(v) = 2v + (1 - v) \log(1 - v)$. The solution is $x(t) = (v(t), y(t))$, where

\[
\begin{align*}
v(t) &= 1 - e^{-t}, \\
y(t) &= f(v(t)) = 2v(t) - (1 - v) t.
\end{align*}
\]

(55)

As $n \rightarrow \infty$, we have that $\bar{z}^{(n)}(t)$ converges almost surely to $x(t)$, uniformly on bounded time intervals (on a suitable probability space).

Notice now that $\nu_{\infty}$ given in (17) is the unique root of the function $f$ in $(0, 1)$. Moreover, the function $\nu(t)$ in (55) establishes a one-to-one correspondence between $(0, \infty)$ and $(0, 1)$, so $\nu_{\infty} = \nu(\nu_{\infty})$, where $\nu_{\infty} = h(v)\nu_{\infty}$. Since $y'(0) > 0$ and

\[
\forall \varphi(x(\nu_{\infty})), F(x(\nu_{\infty})) = y'(\nu_{\infty})
\]

\[
= (1 - \nu_{\infty})(1 - 2\nu_{\infty} + 1) < 0,
\]

(56)

we conclude that $\lim_{n \rightarrow \infty} \bar{z}^{(n)} = \nu_{\infty}$ almost surely. Consequently,

\[
\lim_{n \rightarrow \infty} \nu^{(n)}(\mathbf{\tilde{r}}^{(n)}) = \lim_{n \rightarrow \infty} \tilde{v}^{(n)}(\mathbf{\tilde{r}}^{(n)}) = \nu_{\infty} \quad \text{almost surely.}
\]

(57)

Regarding the Central Limit Theorem, the associated Gaussian process is denoted here by $U = (U_\nu, U_y)$, and we obtain from Theorem 11.4.1 of Ethier and Kurtz [8] that

\[
\sqrt{n}(\tilde{v}^{(n)}(\mathbf{\tilde{r}}^{(n)}) - \nu_{\infty}) \xrightarrow{D} U_x(\nu_{\infty}) - \frac{1 - \nu_{\infty}}{2\nu_{\infty} + 1} U_y(\nu_{\infty})
\]

as $n \rightarrow \infty$.

(58)

The principal points in the calculation of the variance $\sigma^2$ of the asymptotic normal distribution are the following:

\[
\begin{align*}
\Phi(t, s) &= \begin{pmatrix} e^{s-t} & 0 \\
2(e^{s-t} - 1) & 1 \end{pmatrix}, \\
\sigma^2 & = \begin{pmatrix} \nu_{\infty} & -\nu_{\infty}(1 - \nu_{\infty}) \\
-\nu_{\infty}(1 - \nu_{\infty}) & (1 + \nu_{\infty})\nu_{\infty}(2\nu_{\infty} - 1) \end{pmatrix}.
\end{align*}
\]

(59)
Again, by using the well-known properties of variance and covariance and simplifying properly, we obtain formula (21).

5.2.2. Proof of Lemma 8. Notice that we can construct the epidemic process with mutation rate \( v > 1 \) from the process with rate 1, in such a way that the final number of infected individuals in the latter process is no greater than in the former. Consequently, it is enough to prove that

\[
\lim_{n \to \infty} V(n)(\tau(n)) = 1
\]

in probability only for the process with rate \( v = 1 \). Considering such a process, let \( \{\tilde{x}(n)(t)\}_{t \geq 0} \) be as defined previously, and construct from \( \{\tilde{x}(n)(t)\}_{t \geq 0} \) a time-changed Markov chain with the same transitions as \( \tilde{x}(n) \), but with transition functions given by

\[
\beta_{u_0}(v, y) = 1, \quad \beta_{u_1}(v, y) = \frac{v}{1 - v}, \quad \beta_{u_2}(v, y) = \frac{1}{1 - v}. \quad (60)
\]

Of course, this process is defined up to \( \hat{\tau}(n) = \inf \{t \geq 0 : \hat{y}(n)(t)(1 - \hat{y}(n)(t)) = 0\} \).

The solution of the corresponding system of ordinary differential equations is given by

\[
v(t) = t, \quad y(t) = 2t, \quad t \in [0, 1]. \quad (61)
\]

Since \( \{v(n)(t), \hat{y}(n)(t)\} \) converges almost surely to \( (v(t), y(t)) \) uniformly on \( [0, 1] \), we conclude that \( \lim_{n \to \infty} \hat{\tau}(n) = 1 \) almost surely. From this, it follows that \( \lim_{n \to \infty} v(n)(\tau(n)) = \lim_{n \to \infty} \hat{y}(n)(\hat{\tau}(n)) = 1 \) almost surely.

### Appendix

#### The Lambert W Function

The Lambert W function is the multivalued inverse of the function \( w \mapsto we^w \). That is, \( W(z) \) is defined to be the function satisfying

\[
W(z)e^{W(z)} = z. \quad (A.1)
\]

If \( x \) is real, then for \(-e^{-1} \leq x < 0\) there are two possible real values of \( W(x) \) (see Figure 6(a)). The branch that satisfies \( W(x) \geq -1 \) is called the principal branch of the \( W \) function and denoted by \( W_0 \); the branch that satisfies \( W(x) \leq -1 \) is called the lower branch and denoted by \( W_{-1} \). We refer to Corless et al. [12] for more details.

Now let \( 0 < b < a \) and consider the function \( f : [0, 1) \to \mathbb{R} \) given by

\[
f(v) = av + b \log(1 - v). \quad (A.2)
\]

The graph of \( f \) is presented in Figure 6(b). It is not difficult to see that \( f(0) = 0 \), \( f \) is increasing in \([0, 1 - b/a)\) and decreasing in \((1 - b/a, 1)\), and \( \lim_{v \to 1} f(v) = -\infty \). Therefore, \( f \) has a unique root \( \overline{\nu} \) in the interval \((0, 1)\).

To express \( \overline{\nu} \) in terms of the \( W \) function, define \( \alpha = a/b > 1 \), thus \(-e^{-1} < -\alpha e^{-\alpha} < 0\). Notice that \( \overline{\nu} \in (0, 1) \) satisfies \( \overline{\nu} = 1 - e^{-\alpha \overline{\nu}} \), which can be written as

\[
-\alpha e^{-\alpha} = \alpha (\overline{\nu} - 1)e^{\alpha(\overline{\nu}-1)}. \quad (A.3)
\]

Consequently,

\[
\overline{\nu} = 1 + \frac{1}{\alpha} W_0(-\alpha e^{-\alpha}). \quad (A.4)
\]

#### Conflict of Interests

The author declares that there is no conflict of interests regarding the publication of this paper.
Acknowledgments

The author is grateful to CNPq (Grant 303872/2012-8), FAPESP (Grant 2012/22673-4), and PRP-FAEPEX-UNICAMP (Grant 016/13) for financial support. He also thanks the two anonymous referees for valuable suggestions which allowed improving the paper.
