Introduction of a transgenic αβ TCR (V<sub>α2</sub>, V<sub>β8.1</sub>) specific for lymphocytic choriomeningitis virus (LCMV), in the context of H-2D<sup>b</sup> into the genome of C57BL/6 mice, has many effects on the development and selection of T cells in both the thymus and the periphery. These mice produce increased numbers of CD4<sup>+</sup>8<sup>+</sup> mature T cells, all of which express the transgenic TCR, and small numbers of CD4<sup>+</sup>8<sup>-</sup> cells using endogenous TCRs are also produced. This study follows the intrathymic development of T cells in these TCR αβ transgenic mice, in particular the earliest CD4<sup>+</sup>8<sup>-</sup> stages. As expected, the transgenic TCR is expressed on the cell surface at an earlier developmental stage than endogenous TCRs in nontransgenic littermate controls. Of the three major subsets expressing the heat-stable antigen (HSA), only the most mature, the CD25<sup>-</sup>CD44<sup>-</sup> expresses the transgenic TCR, and the earlier CD25<sup>-</sup>CD44<sup></sup> and CD25<sup></sup>CD44<sup>-</sup> do not. Furthermore, in contrast to other TCR αβ transgenic lines, TCR γδ lineage cells appear to develop normally.

KEYWORDS: T-cell development, T-cell receptor, transgenic mice, immature thymocytes.

INTRODUCTION

The development of mature T lymphocytes is a complex process, involving proliferation and differentiation of immature precursor cells through a series of quite well-defined stages. CD4<sup>-</sup>CD8<sup>-</sup> prothymocytes (originating in the fetal liver or bone marrow) colonize the thymus and subsequently proliferate and differentiate to give rise to CD4<sup>+</sup>8<sup>-</sup> intermediates and ultimately functional cells expressing either CD4 or CD8 (Fowlkes et al., 1985; MacDonald et al., 1988b; Scollay et al., 1988). During this process, the T-cell receptor (TCR) αβ and γδ genes are rearranged and expressed, and various other phenotypic markers are acquired or lost (Fowlkes and Pardoll, 1989; Pearse et al., 1989). Positive and negative selection events limit the repertoire of expressed TCR αβ genes to avoid autoreactivity and account for MHC-restricted antigen recognition (Kappler and Marrack, 1987; von Boehmer, 1990). This latter selection phenomenon has come under closer scrutiny due to the recent availability of transgenic mice expressing TCR αβ with defined antigen and MHC specificity (Sha et al., 1988; Teh et al., 1988; Berg et al., 1989; Kaye et al., 1989; Pircher et al., 1989a). In the present study, we have analyzed immature CD4<sup>-</sup>CD8<sup>-</sup> T cell subsets that would normally not express surface TCR from TCR αβ transgenic mice in order to assess the effects of premature TCR expression on early T-cell development.

RESULTS

Increase of Immature (CD4<sup>-</sup>8<sup>-</sup>) Thymocytes in TCR Transgenic Mice

We have previously described transgenic mice expressing a TCR (V<sub>β8.1</sub>, V<sub>α2</sub>) that is specific for LCMV in the context of H-2D<sup>b</sup> (Pircher et al., 1989a). On the selective MHC background (H-2<sup>b</sup>), CD8<sup>-</sup> T cells bearing the transgene are positively selected (Pircher et al., 1989a; Ohashi et al., 1990). As shown in Fig. 1 and Table 1, such transgenic thymi are smaller than littermate controls in adult (8–12 wk) H-2<sup>b</sup> mice; however, the imma-
tured CD4⁺CD8⁻ subset is increased both in percentage and in absolute numbers in the transgenics. On the H-2d background, where there is no positive selection of the transgene-bearing cells, the thymi are of a similar size to their littermate controls, but still have increased numbers and percentage of the CD4⁺CD8⁻ subset (Table 1).

### Expression of Transgenic TCR on CD4⁺CD8⁻ Thymocytes

The transgenic TCR expressed in these mice can be detected by mAbs directed against Vβ1 (KJ16) or Vβ2 (B20.1). As shown in Fig. 2, a large proportion of CD4⁺CD8⁺ thymocytes expressed both the transgenic TCR α and β chains. Furthermore, staining with mAbs directed against CD3 or TCR αβ gave similar patterns as Vβ1 or Vβ2 staining, indicating that few (if any) nontransgenic TCR αβ were expressed. The same staining patterns were observed on CD4⁺CD8⁺ thymocytes in the presence (H-2b), or absence (H-2d) of the selecting element, indicating that this has no effect on the expression of the transgenic TCR.

### Subsets of CD4⁺CD8⁻ Thymocytes in TCR Transgenic Mice

CD4⁺CD8⁻ thymocytes can be subdivided into subsets on the basis of expression of various surface markers. Among the most useful markers are heat-stable antigens (HSA), IL-2 receptor α chain (CD25), and Pgp-1 (CD44), which together define four major subsets (MacDonald et al., 1988b; Scollay et al., 1988). According to current views (Pearse et al., 1989; Petrie et al., 1990), HSA⁺CD25⁺CD44⁺ immature precursors give rise sequentially to HSA⁺CD25⁺CD44⁻ and subsequently HSA⁻CD25⁺ CD44⁻ subsets, the latter being immediate precursors of CD4⁺CD8⁺ cells (Wilson et al., 1989; Petrie et al., 1990). The fourth subset (HSA⁻CD25⁺CD44⁺) is believed not to belong to the normal generative lineage and may result from an aberrant selection process (Crispe et al., 1987; Scollay et al., 1988).

*Data expressed as absolute number of cells per thymus (x10⁶±SD, and are the mean of four (H-2b) and nine (H-2d) experiments each using pools of two to eight mice.*
Comparison of these major CD4-8⁻ subsets in adult H-2ᵇ TCR transgenic mice and littermate controls (Table 2, Fig. 3) revealed no significant differences in the two putatively most immature populations (HSA⁻CD25⁻CD44⁻ and HSA⁺CD25⁺CD44⁺). In contrast, the putatively most mature (HSA⁺CD25⁻CD44⁻) CD4-8⁻ subset was substantially increased in absolute numbers in the transgenics, and the "aberrant" (HSA⁺CD25⁺CD44⁺) subset was much reduced. Similar results were obtained from transgenic mice on the H-2ᵇ background.

Expression of Transgenic TCR on CD4-8⁻ Subsets

The CD4-8⁻ subsets described before were analyzed for expression of the transgenic TCR. Transgenic TCR (Vβ8.1 or Vα2) was found on the relatively mature HSA⁺CD25⁻CD44⁻ subpopulation and was not detected on the less mature HSA⁺CD25⁺CD44⁻ and HSA⁺CD25⁺CD44⁺ subsets (Fig. 4, and data not shown). The HSA⁻ subset could not be analyzed for TCR expression in the transgenics due to the small number of cells present; however, this subset was readily detectable in the control littermates, where many cells expressed Vβ8.2 (data not shown; Budd et al., 1987; Fowlkes et al., 1987).

Expression of TCR γδ in TCR αβ Transgenics

Several studies have suggested that expression of TCR β transgenes leads to allelic exclusion of endogenous TCR γ genes as well as TCR β (Fenton et al., 1988; Uematsu et al., 1988; von Boehmer et al., 1988; Pircher et al., 1990). As shown in Fig. 5 and Table 3, TCR γδ⁺ cells were readily detectable in the CD4-8⁻ subset of the H-2ᵇ or H-2ᵇ TCR αβ transgenics described here. Although the relative percentage of TCR γδ⁺ cells was lower in transgenics than in littermate controls, the absolute number was not significantly different between the two groups (Table 2).

3), thus suggesting that the TCR γδ lineage develops normally in these TCR αβ transgenic mice.

**Other Phenotypic Markers on TCR Transgenic CD4^-8^- Thymocytes**

We also compared the expression of other surface markers on H-2b TCR transgenic versus control CD4^-8^- thymocytes (Fig. 6). Several markers that are normally associated with the degree of T-cell maturation (such as CD5 and Mel-14) were expressed at higher levels on the transgenic population. On the other hand, a marker associated with cell division (RL73) was expressed at reduced levels on transgenic versus control CD4^-8^- cells. This latter result was confirmed by a reduced frequency of large blast cells (assessed by FLS) among CD4^-8^- transgenic thymocytes (data not shown).

**Analysis of "Immature" CD4^-8^- Thymocytes in TCR Transgenic Mice**

In normal mice, differentiation of CD4^-8^- to CD4^+8^- thymocytes frequently occurs via a rapidly cycling CD4^-8^- blast intermediate that expresses high levels of HSA and no detectable CD3 (MacDonald et al., 1988a; Shortman et al., 1988). As shown in Fig. 7, all CD4^+8^- thymocytes in H-2b TCR transgenic mice expressed high levels of CD3 (as expected), and low levels of HSA as compared to control littermates. Furthermore, few blast cells were detectable (by FLS analysis) in the transgenic CD4^-8^- population.
thymocytes are lacking in the TCR transgenic thymus. However, CD4^−8^ cells with a lower level of CD8 are found in the transgenic thymus in numbers comparable to that of the littermate controls (1.5±0.4% and 1.6±0.6%, respectively; see Fig. 1). As noted elsewhere, this phenotype may correspond to relative immaturity of these cells (Shortman et al., 1988). The recently described CD4^−8^−3^−"immature" thymocyte showing a similar phenotype and morphology (Shortman et al., 1988; Matsumoto et al., 1989; Hugo et al., 1990) was also virtually undetectable in these transgenic mice.

**DISCUSSION**

It is well established that the precursors of mature T lymphocytes are contained within the CD4^−8^ thymocyte subset (Fowlkes et al., 1985; Crispe et al., 1987; Shimonkevitz et al., 1987; Scollay et al., 1988). The developmental sequence occurring within that population is now more clearly understood (Pearse et al., 1989; Petrie et al., 1990), although the precise events that direct this differentiation are not. In this communication, we have analyzed CD4^−8^ thymocytes from mice expressing a transgenic TCR αβ in order to gain further insights into early T-cell development. In normal mice, TCR αβ is first expressed at the CD4^−8^ stage of thymus development and hence TCR expression in transgenic mice allows cross-correlations with other phenotypic markers believed to define early developmental stages.

The current consensus view of lineage relationships among major CD4^−8^ subsets (Fowlkes and Pardoll, 1989; Petrie et al., 1990) holds that HSA^+^CD25^−^CD44^−^ early precursors differentiate through a HSA^+^CD25^−^CD44^−^ intermediate stage to become HSA^+^CD25^−^CD44^−^ blast cells prior to acquisition of CD4 and/or CD8. Consistent with this model, the present results indicate that only the latter (presumably most mature) CD4^−8^− population expresses detectable transgenic TCR, and the putatively more immature CD4^−8^− subsets do not. In contrast to our findings, Teh et al. (1990) have recently reported expression of transgenic TCR αβ on essentially all CD4^−8^− thymocytes. The reason for this apparent discrepancy is not clear; however, it should be noted that the TCR α and TCR β transgenic constructs used by Teh et al. (1990) were large genomic fragments (Teh et al., 1988; Uematsu et al., 1988), whereas the TCR constructs used here were TCR α and β cDNA clones coupled to a H-2K promoter and Ig heavy-chain enhancer (Pircher et al., 1989b). It is thus possible that these differences in regulatory elements lead to differential ontogeny of expression of the two TCR transgenes in vivo. Failure to express the transgene on the early CD4^−8^− subsets is not due to lack of function of the H-2K promoter because H-2K^b^ is expressed at high levels on all of these subsets (data not shown).

In contrast to the three major HSA^+^ subsets of CD4^−8^− thymocytes, HSA^+^CD4^−8^− cells appear not to belong to the generative lineage (Scollay et al., 1988; Fowlkes and Pardoll, 1989). Furthermore, this HSA^−^ subset is peculiar in that it appears late in development and most of the cells express TCR αβ with a strong preference for the V_{β8.2} variable domain (Budd et al., 1987; Fowlkes et al., 1987). Interestingly, HSA^+^CD4^−8^− thymocytes were dramatically reduced in our TCR αβ transgenic mice. In contrast, Teh et al. (1990) reported large numbers of HSA^−^ thymocytes (~20% of
FIGURE 5. Presence of TCR γδ cells in the H-2^d CD4^-CD8^- thymus population. Expression of TCR αβ or TCR γδ correlated with HSA expression on CD4^-CD8^- thymocytes from transgenic or littermate controls. Cells were stained with anti-HSA FITC (direct conjugate) and anti-TCR αβ or anti-TCR γδ biotin conjugates, followed by PE-Av. Live gating to exclude dead cells and debris, quadrants to show the position of the negative controls, and analyses were performed as described in Fig. 1.

In interpreting this dramatic difference, it is noteworthy that the transgenic TCR β chain of Teh et al. (1990) encodes V_β2, whereas the β chain studied here encodes V_β1. Thus, it may be that V_β2 expression is essential (even in transgenic mice) for the development of the HSA^-CD4^-CD8^- subset. Whether this subset arises via aberrant positive selection of V_β2^+CD4^-CD8^- thymocytes (von Boehmer, 1990) or by some other mechanism remains to be determined.

FIGURE 6. Changes in the level of expression of other phenotypic markers. Single-parameter profiles of various surface antigens on total CD4^-CD8^- thymocytes from the H-2^d transgenics or their littermate controls. Cells were stained with culture supernatants, followed by a goat antirat Ig FITC conjugate. Shaded profiles are from transgenics and the unshaded from the littermate controls.
Transition of thymocytes from the CD4-CD8- to CD4+CD8+ compartment may involve an intermediate CD4-CD8- (MacDonald et al., 1988a; Shortman et al., 1988) or CD4+CD8- (Hugo et al., 1990; Matsumoto et al., 1989) cell expressing little or no detectable surface TCR. In mouse, the "immature CD8" population is rapidly cycling and exhibits high levels of HSA. By these criteria, no immature CD4-CD8- thymocytes could be detected in TCR αβ transgenic mice. The absence of this intermediate subset may result from accelerated differentiation of the immediate CD4-CD8- precursors of these cells. Indeed, HSA-CD25-CD44+ thymocytes were present in elevated numbers in TCR αβ transgenic mice of both the H-2b (selecting) and H-2d (nonselecting) backgrounds. In addition, this subset expressed enhanced levels of several phenotypic markers (CD5, Mel-14) and a decreased proportion of cycling cells, both traits that are usually associated with T-cell maturation. Therefore, the premature expression of surface transgenic TCR, even if it cannot be positively selected (as on the H-2d background), may be associated with accelerated maturation of immature thymocytes. Furthermore, these data provide evidence that the "immature," CD4-CD8- or CD4-CD8-3- subsets are not obligatory stages in the differentiation from CD4-CD8- to CD4-CD8+ cells (Wilson et al., 1989; Petrie et al., 1990).

Considerable controversy surrounds the developmental relationship between TCR αβ and TCR γδ lineages (Fowlkes and Pardoll, 1989). In this context, several studies have indicated that introduction of a rearranged TCR β transgene effectively inhibits further gene rearrangement at the TCR γ locus, presumably due to some transacting allelic exclusion mechanism (Fenton et al., 1988; von Boehmer et al., 1988), and other reports have suggested that a partial inhibitory effect of transgenic TCR β on TCR γ rearrangement occurs, but that the TCR γδ population remains unchanged (Pircher et al., 1990). In other studies using γ and/or γδ transgenic mice, complete inhibition (Bonneville et al., 1989), no effect (Dent et al., 1990; Ishida et al., 1990), or enhancement (Ferrick et al., 1989) of the TCR γδ lineage have been reported. In the TCR αβ transgenic mice reported here, TCRγδ+ cells were readily detected in the CD4-CD8- thymocyte subset and absolute numbers of these cells were identical to the values obtained in control littermates. In addition, the TCR γδ-expressing dendritic epidermal T cells (DETC) isolated from the skin of these TCR αβ transgenic mice were shown to be indistinguishable (both in absolute numbers and Vγ usage) from those found in their littermate controls (P. Ohashi et al., unpublished data). Thus, it seems that TCR αβ and TCR γδ lineages are controlled independently in these animals; however, it is possible that TCR γδ cells develop normally due to a delayed expression of the TCR αβ transgene (see before).
In conclusion, the premature expression of a defined TCR $\alpha\beta$ transgene provides a useful model system in which to test the predicted developmental lineage of immature (CD4$^-$8$^-$) thymocyte subsets. Furthermore, the comparison of CD4$^-$8$^-$ thymocytes expressing different transgenic V$\beta$ domains may ultimately lead to new insights regarding the developmental origin of the HSA-CD4$^-$8$^-$ subset.

**MATERIALS AND METHODS**

**Mice**

All the mice used in this study were bred and maintained at the Swiss Institute for Experimental Cancer Research (Epalinges, Switzerland). The transgenic TCR (V$\alpha_2$,J$\alpha_{28,1}$/V$\beta_{8,1}$,DBJ$\beta_{2,4}$,C$\beta$) was derived from a LCMV/H-2$^b$-specific cytotoxic T-cell clone P14 (Pircher et al., 1987). Transgenic males on either a C57BL/6 (H-2$^b$) or Balb/c (H-2$^d$) genetic background (Pircher et al., 1989a) were heterozygously bred with normal MHC compatible 6–8-week-old females. In this way, a colony of TCR $\alpha\beta$ transgenic mice on the selective (H-2$^b$) or nonselective (H-2$^d$) background and their nontransgene bearing littersmates were established. Litters were screened for transgene-bearing mice at approximately 4 weeks of age by staining peripheral blood lymphocytes with the monoclonal antibody KJ16, which binds the V$\beta$8 and V$\beta$12 TCRs, followed by goat antirat Ig-FITC, and then counterstaining with a mixture of anti-CD8 biotin and either anti-CD4-PE or anti-CD4 biotin and finally PE-streptavidin. The percent of V$\beta$8-bearing T cells was 15–20% for the nontransgene-bearing littermates and 85–90% for the transgenics.

**Isolation of Immature Thymocytes**

CD4$^-$CD8$^-$ thymocytes were purified from total thymus by treating cell suspensions at 5x$10^7$/mL in DMEM supplemented with glutamine and Hepes buffer and containing 1% FCS, with previously determined concentrations of the anti-CD4 mAb RL1.172.4 (Ceredig et al., 1985) and the anti-CD8 mAb 3.168.8.1 (Sarmiento et al., 1982) for 20 min on ice, followed by 45 min at 37 °C after the addition of rabbit complement (final concentration 1/20, supplied by The Buxted Rabbit Company, Buxted, UK) and 10 units/mL of DNase I (Boehringer Mannheim GmbH, Mannheim, West Germany) to prevent excessive clumping of dead cells and debris. Dead cells were removed by centrifugation over Isopaque-Ficoll (Pharmacia, Uppsala, Sweden). To ensure purity of the final preparation, this entire procedure was repeated with the cells at 10$^7$/mL. CD4$^+$ thymocytes were prepared in the same manner with the omission of the anti-CD8 antibody. In both cases, the resultant cells were greater than 98% pure.

**Monoclonal Antibodies**

Culture supernatants were prepared from hybridomas grown in the laboratory as follows. Anti-CD3, 17A2 (Miescher et al., 1989/1990); anti-V$\alpha_2$, B20.1 (B. Malissen et al., manuscript in preparation); anti-V$\beta_{8,1,8,2}$, KJ16.133.18 (Haskins et al., 1984); anti-CD44 (PgP1), IM7.8.1 (Trowbridge et al., 1982); anti-CD25 (IL2R$\alpha$), PC61.5 (Ceredig et al., 1985); Mel-14 (Gallatin et al., 1983); anti-CD5, 53-7.3 (Ledbetter and Herzenberg, 1979); and RLI.73.2 (MacDonald et al., 1985). Biotin conjugates were prepared in the laboratory, and were as follows: anti-CD8, 53.6.72 (Ledbetter and Herzenberg, 1979); anti-CD4, GK1.5 (Dialynas et al., 1983); anti-HSA, M1/69 (Springer et al., 1978) and anti-CD25 (as before). Anti-TCR $\alpha\beta$, H57.597 (Kubo et al., 1989) and anti-TCR $\gamma$, GL3 (Goodman and Lefrancois, 1989), both biotin conjugates, were the kind gift of J.-P. Rosat, WHO Immunology Research and Training Unit, Epalinges, Switzerland. Fluorescein (FITC) conjugates of anti-CD8, H35-17.2 (Goldstein et al., 1982) and anti-HSA, M1/69 (as before) were prepared in the laboratory. Anti-CD4-PE was purchased from Bectin Dickinson, Mountain View, CA. Second-stage reagents were purchased as follows: Goat antirat Ig-FITC (Tago, Inc., Burlingame, CA), Goat antirat Ig-PE (Southern Biotechnology Associates, Inc., Birmingham, AL), PE-Av (R-phycocerythrin-streptavidin, from Caltag Laboratories, San Francisco, CA), and PE-TR-Avidin (R-phycocerythrin (PE), covalently bound to texas red (TR), and coupled to avidin; with an excitation wavelength characteristic of PE and emission wavelength characteristic of TR; from Southern Biotechnology Associates, Birmingham, AL).
Staining Procedures

Single two-color and three-color staining of thymocytes was performed as previously described (Shortman et al., 1988; Wilson et al., 1988, 1989). Analysis of these stained cells was done with a FACS II for the single staining and a FACScan for the two- and three-color fluorescence (both Flow Cytometers were supplied by Becton Dickinson, Mountain View, CA).

ACKNOWLEDGMENTS

We thank Christian Knabenhans and Pierre Zaech for their patience and skill with the flow cytometric analysis, Bernard Malissen for his kind gift of the B20.1 monoclonal antibody, and Anna Zoppi for her help in preparation of the manuscript.
