Gold/chitosan nanocomposites were synthesized and evaluated as a therapeutic agent for the photothermal therapy. Gold nanoparticles (Au NPs) with controllable optical absorption in the near infrared (NIR) region were prepared by the reaction of chloroauric acid and sodium thiosulfate. To apply these particles to cancer therapy, the bare Au NPs were coated with chitosan (CS), O-carboxymethyl chitosan (CMCS), and a blend of CS and CMCS for utilizations in physiologic conditions. The surface properties, optical stability, and photothermal ablation efficiency on hepatocellular carcinoma cells (HepG2) and human dermal fibroblast cells (HDF) demonstrate that these gold nanocomposites have great potential as a therapeutic agent in vitro tests. The CS-coated nanocomposites show the highest efficiency for the photo-ablation on the HepG2 cells, and the CS and CMCS blended coated particles show the best discrimination between the cancer cell and normal cells. The well-controlled NIR absorption and the biocompatible surface of these nanocomposites allow low-power NIR laser activation and low-dosage particle injection for the cancer cell treatment.

1. Introduction

The use of nanoparticles (NPs) in biomedical field is one of the most important branches of nanobiotechnology. Many biomedical applications require nanoparticles with low toxicity, biocompatibility, and stability with high preferential accumulation in the target tissue or organ [1]. Polymer-nanoparticle composites may possess the unique property superior to that of either the polymer or nanoparticles. Metal nanoparticles with polymer coatings or dispersed in polymeric matrices display the increased stability, improved processability, recyclability, and solubility in a variety of solvents [2].

Gold nanoparticles (Au NPs) are attracting enormous attentions in applications for immunoassay [3, 4], drug delivery [5], contrast enhancement, and thermal therapy for tumor treatment [6–8], due to their nanoscale size, oxide-free components, bioconjugation property, biocompatibility, and unique optical properties.

Thermal therapy, also termed as hyperthermia, has thousands years history as one of most important methods for the tumor treatment [9]. In this technique, moderate heating is generated in the target region, resulting in tumors selectively destroyed, due to their reduced heat tolerance compared to normal tissue [10]. In the past decades, because many new heating sources such as radiofrequency [11], microwave [12], magnetic field [13], and laser [9] were employed, there were remarkable progresses achieved in this area. Photothermal therapy (PT) is a promising field within thermal therapy, incorporating laser techniques and photoabsorbing agents. Light absorbing dyes, chemical photosensitizers, and solid optically responsive nanomaterials have been applied as the photoabsorbing agents in PT [9]. For small metal nanoparticles, their optical properties are dominated by collective oscillation of conduction electrons. An absorption band results when the incident photon frequency is resonant with the collective oscillation of the conduction band electrons, and this is known as the surface plasmon resonance (SPR) [14]. Au NPs possess strongly enhanced visible and near infrared light absorption, which is several orders of magnitude more intense compared to conventional chromophores. Various gold-based nanostructures with NIR
absorption have been developed. Gold nanospheres [15],
gold nanoshells [7], gold nanorods [16], and gold nanocages
[17] are the popular nanostructures that have been demon-
strated in photothermal therapeutics due to their strongly
enhanced absorption in the visible and NIR regions on
account of their SPR effects.

In our work, Au NPs with NIR absorption were prepared
by the one step reaction of chloroauric acid and sodium
thiosulfate. Their NIR absorption wavelengths were well
controlled by adjusting molar ratio of HAuCl4/Na2S2O3
[18]. These Au NPs were coated with chitosan- (CS)-
based coatings and used as a therapeutic agent for the
photothermal ablation of cancer cells. Chitosan is a biobased
polysaccharide derived from shrimp and crab shells [19]. It
is nontoxic, biodegradable and biocompatible, and has good
processability [20, 21]. The cost associated with chitosan is
much lower than that of other polymer coatings or chemical
compounds, for example, polyethylene glycol (PEG) that
are often used to protect and stabilize the nanoparticles by
many researchers [5]. Hepatocellular carcinoma is the most
common primary malignant tumor of the liver. It affects
greater than half a million patients worldwide. US liver-
related cancer deaths account for 4% of all cancers or about
20,000 deaths annually. Two anchorage-dependent cell lines,
hepatocellular carcinoma cell line (HepG2), and control cell
line of human dermal fibroblast (HDF) were selected for
the estimation of laser ablation efficiency of these novel
gold nanocomposites. The efficacy was evaluated by live/dead
stain images following photothermal ablation. These gold
nanocomposites show great ability for laser ablation, and the
surface coating components play a very important role for
selectivity to certain cancer cells. In addition, this composite
material offers new and desirable advantages for cancer
treatment. Besides the optically tunable gold nanoparticle
which, 3 mM sodium thiosulfate (Na2S2O3
5H2O, Aldrich,
99.999%) solution was added into 1.71 mM chloroauric
acid (HAuCl4·3H2O, Alfa Aesar, Au 49.68%) solutions with
desired volume ratio at room temperature and vortexed for
20 seconds for uniform mixing. All the water used in the
experiments was purified by a Thermo Scientific Easypure
II system, with a resistivity of 18.2 MΩ cm.

2. Experimental

2.1. Preparation of Au Nanoparticles. Au NPs were pre-
pared by the method we reported before [18, 22]. In
which, 3 mM sodium thiosulfate (Na2S2O3·5H2O, Aldrich,
99.999%) solution was added into 1.71 mM chloroauric
acid (HAuCl4·3H2O, Alfa Aesar, Au 49.68%) solutions with
desired volume ratio at room temperature and vortexed for
20 seconds for uniform mixing. All the water used in the
experiments was purified by a Thermo Scientific Easypure
II system, with a resistivity of 18.2 MΩ cm.

2.2. Preparation of Carboxymethylated Chitosan. Low mol-
ecule weight chitosan (Sigma-Aldrich, MW 50–190 K) was
used for the surface coating of the Au NPs. Based on this chi-
tosan, O-carboxymethyl chitosan (CMCS) was synthesized as
the reported method [23, 24]. Briefly, 15 g sodium hydroxide
was dissolved in a 20:80 mixture of deionized water and
isopropanol (100 mL) in a 500 mL flask. 10 g chitosan was
added to the flask to swell and alkalinize at 50°C for 1 h. 15 g
monochloroacetic acid (C1H2ClCO2H, 99%, Acros Organics)
dissolved in 20 mL isopropanol and added into the
reaction mixture dropwisely in 30 min and reacted under
vigorous agitation for 4 h at 55–60°C. Adding 200 mL 80%
ethyl alcohol stopped the reaction. The product was filtered
and repeatedly rinsed by 80% ethyl alcohol, to desalt and
dewater, until the pH value of the washing solution was less
than 8.0. Finally, the product was vacuum dried for 1 day at
40°C.

2.3. Preparation and Purification of Au NPs with Chitosan
Based Coatings. Stock solution of chitosan was prepared
by dispersing chitosan (1 g) in 0.7% acetic acid solution
(100 mL). CMCS solution was prepared by directly dis-
solving CMCS (1 g) in 100 mL DI water. CS and CMCS
solutions were purified by centrifuge at 1000 rpm for 10 min,
to remove the little amount of insoluble residuals, and
then were dialyzed (Spectrum Dialysis Membranes, MWCO
3 KDa) for 2 days. The chitosan-coated Au NPs (Au/CS),
CMCS coated Au NPs (Au/CMCS), and CS and CMCS
blended coated Au NPs (Au/(CS+CMCS)) were prepared by,
respectively, adding CS solution, CMCS solution, or CS
and CMCS blending solution (CS and CMCS solutions were
premixed) dropwisely into the as-synthesized gold particle
suspensions, with vigorous agitation. The ratio between CS
or CMCS to Au NPs was controlled as 0.2 mg CS or CMCS
per OD Au NP suspension and between CS and CMCS
blending to Au NPs is (0.15 mg CS + 0.05 mg CMCS) per
OD Au NP suspension (OD is the optical density). Then
these samples were set on the rocking bed for 1 day. In the
end the gold nanocomposite suspensions were concentrated
and separated from the solution by centrifugation at 1000 g
for 20 min. This step will remove the byproducts in solution
and the extra chitosan. Then the centrifuged pellets were
dispersed in sterilized DI water to a concentration of
25 OD/mL and stored at 4°C for the subsequent studies.

2.4. Characterization of Au NPs. The optical absorption
of Au NPs was measured by a UV-Visible spectrophotometer
(Cary-50Bio, Varian). A Zetasizer (Nano-ZS90, Malvern)
was used to assess the surface charge of the nanoparticle
suspensions. A FEI Tecnai F30 transmission electron micro-
scope (TEM) operated at 200 KV was used to determine the
morphology of Au NPs. Several Au NPs suspensions that
have different NIR peak wavelength were carefully prepared
for the photo-induced temperature rising measurement.
1 mL of the Au NP suspensions were added into the wells
to make the surface charge of the nanoparticle
suspensions. A FEI Tecnai F30 transmission electron micro-
scope (TEM) operated at 200 KV was used to determine the
morphology of Au NPs. Several Au NPs suspensions that
have different NIR peak wavelength were carefully prepared
for the photo-induced temperature rising measurement.
1 mL of the Au NP suspensions were added into the wells
of tissue culture plate (Multiwell, Primaria 24 Well), with
the concentration of 1 OD/mL. A laser with 817 nm centered
wavelength generated by FAT-System (Coherent, CA) was
shone on the gold suspension. The laser spot has the same
area with the well, and the power of the laser was fixed as
1 W/cm². An infrared thermometer (CSmicro, Optris
GmbH, Germany) detecting the temperature of the Au NP
suspension was fixed 10 cm above the media.

2.5. Photothermal Ablation Study. All cell lines were obtained
from ATCC (Manassas, VA). Human dermal fibroblasts cell

3. Results and Discussion

3.1. Preparation of Gold Nanoparticles with Desired Near Infrared Absorption. In our previous work [18, 25], a convenient method was developed to synthesize Au NPs with controllable NIR absorption. Au NPs were synthesized by one-step reaction of chloroauric acid and sodium thiosulfate, without assistance of additional templates, capping reagents, or seeds assembly. The synthesized products consist of nanoparticles with different shape and size including small spherical colloid gold particles (<5 nm) and nonspherical gold crystals. The nonspherical gold crystals are mainly the truncated octahedron, pentagons, and cuboctahedron, as well as the triangular-shaped plate structures [18]. Two absorption peaks due to the surface plasmon resonance are observed from these samples. The first SPR peak centered at around 530 nm is the characteristic SPR of the spherical colloid gold particles, and the second SPR component is higher at NIR band, which is attributed to the multipolar SPR band from the nonspherical Au NPs [18, 25]. Since the NIR absorption wavelengths increase with increasing temperatures, conditions were optimized to obtain the desired heating effects.
The molar ratio of HAuCl₄/Na₂S₂O₃, adjusting the molar ratio of HAUCl₄/Na₂S₂O₃ during the reaction controlled the absorption wavelength of the Au NPs. These products were further purified by the centrifugation to remove the spherical colloid gold particles, improving the NIR absorption. Figures 1(a) and 1(b) are the Z-contrast STEM images of the as-synthesized Au NPs and the same batch sample purified with centrifugation. The purified product possesses the NIR absorption wavelength at 820 nm. The temperature of the NIR absorbing Au NP suspension induced by the NIR laser radiation is affected by the concentration of nanoparticles, laser power, exposure time, and the absorbing wavelength of the Au NPs [26]. Figure 2 compares the heating effect of the Au NPs suspensions with NIR peak at 820 nm, 880 nm, 980 nm, and 1070 nm, respectively (showing in the insert figure) under the 817 nm wavelength diode laser (1 W/cm²) exposures. After 3 minutes, the temperature reaches to 50.8, 48.2, 46.4, and 41.2 °C for the particles from low wavelength to high wavelength, respectively. The gold sample that has the NIR peak more close to the wavelength of laser source shows the best heating effect. The effective control of the NIR absorption of the gold nanoparticles for matching the wavelength of the laser source enhances the hyperthermia treatment. Meanwhile, the NIR wavelength is considered as the best light source for the photothermal therapy, because it is minimally absorbed by the normal tissues components of water and hemoglobin and can transmit deeply in the body.

3.2. Chitosan-Based Coatings on the Gold Nanoparticles. Chitosan is a cationic polysaccharide of D-glucosamine and N-acetyl-D-glucosamine and has been shown to be a highly biocompatible material and have antibiotic properties. To improve its solubility or achieve new functionality, chemical modifications of chitosan were conducted and many derivatives have been synthesized. For example, modifications can be synthesized by carboxylation of the hydroxyl or amine groups in chitosan structure [20], resulting in the O-carboxymethyl chitosan or N-carboxymethyl chitosan respectively. O-carboxymethyl chitosan is achieved by substituting parts of the –OH at C-6 position of glucosamine units with –CH₂COOH. Therefore, the reactive ligands such as –COOH and –NH₂ groups are amenable to chemical functions. Others have reported the stabilization of GNP with chitosan. As chitosan in solution is protonated and
positively charged, it can be adsorbed onto the surfaces of gold nanoparticles, stabilizing and protecting the nanoparticles [27–29]. As-synthesized Au NPs present strongly negative surface charge (around $-40 \text{ mV}$) allowing the positive charged chitosan tightly coated onto gold surface via electrostatic interaction.

Figures 3(a), 3(b), 3(c), and 3(d) show the high-resolution TEM images of the Au NPs without coating, Au/CS, Au/CMCS, and Au/(CS+CMCS) nanocomposites, respectively. The as-synthesized bare Au NPs have a 1-2 nm thin layer on their surface. Comparing to the bare Au NPs, Figures 3(b)–3(d) show the chitosan-based coatings effectively cover the gold NPs uniformly, forming a 2–5 nm thick layer on the gold surface.

Table 1 lists the hydrodynamic diameter and the surface charge of the gold nanoparticles with different chitosan-based coatings in water. The chitosan-based coating significantly changed the surface property of the gold nanoparticles. The average particle size of the bare gold nanoparticles is 36 nm; after being coated with polymer, the hydrodynamic diameter of Au/CS, Au/CMCS, and Au/(CS+CMCS) reaches 290, 236, and 262 nm, respectively. Meanwhile, their surface charge changes from $-43.5 \text{ mV}$ to $+43.8$, $+20.2$ and $+24.3 \text{ mV}$, respectively.

Figure 4 shows the optical stability of the Au NPs with different coatings in (a) PBS solution and in (b) 1 wt.% NaCl solution. Since the physiologic salinity is near 1%, optical properties of Au NPs were simulated in these solutions. The optical stabilities were measured by monitoring the optical absorbance of the Au NPs at their NIR peak wavelength as function of time. These nanoparticles have similar behavior in the PBS and NaCl solution. CMCS-coated particles show the highest stability, and there is no obvious decrease in its optical absorption in 3h. The CS and CMCS blended coated particles also show good stability, with a decrease in its absorbance less than 10%. The most unstable particles are the bare Au NPs. Its absorbance decreases more than 70% in saline environment. The Au/CS nanocomposites are more stable than the bare particles, but less stable than the Au NPs with CMCS component in the coating. The decrease of NIR absorption of the bare Au NPs results from interparticle coupling effect [30, 31], in which its stabilized surface layer was disturbed due to the high ion strength, causing the particle aggregation (irreversible coalescence). This behavior may greatly decrease the efficiency of photothermal ablation. Chitosan-based coatings greatly improve the optical stability of the Au NPs. The instability of the Au/CS NPs mainly results from the sedimentation of particles caused by the agglomeration (reversible coalescence) of chitosan coating. At the pH value above 6, the solubility of chitosan becomes worse. CMCS has the best solubility in all pH ranges except its isoelectrical point [23]. The good solubility and the

increased chain flexibility [32] of CMCS may prevent the coupling effect and the sedimentation of the particles.

By adjusting the surface components, the surface charge of the Au NPs can be modified. Figure 5 shows the zeta potential of Au NPs with different chitosan coatings as function of the pH value. The isoelectric points (IEP) of Au/CMCS, Au/(CS+CMCS), and Au/CS nanocomposites are 6.1, 7.1, and 7.7, respectively. IEP of CMCS is close to value (5.5) reported by Zhao et al. [33]. CMCS presents amine and carboxylic acid groups in its structure. In solution, the groups turn to the ion state, $-\text{NH}_3^+$ and $-\text{COO}^-$, respectively, which improves the solubility of CMCS. Only at its IEP, the number of $-\text{NH}_3^+$ is equal to that of $-\text{COO}^-$, resulting in the deceasing of solubility. Au/CS particle shows much higher IEP value than that of the Au/CMCS particles, since the CS only presents the positively charged groups ($-\text{NH}_3^+$). The IEP of the Au/(CS+CMCS) particle is 7.1, between the those of Au/CMCS and Au/CS. This shows that the surface charge of Au NPs can be tuned by the chitosan components on their surface, since CMCS possesses more negatively charged characteristic than CS.

3.3. Photothermal Ablation of the HepG2 Cells. Figures 6 and 7 show the live/dead stain images of the HDF and HepG2 cells after being exposed to the 817 nm NIR laser at 5 W/cm², 2 min. The live/dead stain provides a two-color fluorescence assay of cell viability based on plasma membrane permeability, for reliably and quantitatively distinguishing live and dead cells. The live cells show the green color and dead cells show the red color. The statistical cell death ratio of HDF cells and HepG2 cells counted from the live/dead stain images are shown in Figure 8.

Without incubation with Au NPs, cells do not exhibit obvious ablation after the laser irradiation at 5 W/cm², 2 min, as shown in Figures 6(b) and 7(b). The bare Au NPs do not show significant photo-destruction on either cell lines (Figures 6(c) and 7(c)), due to the interparticle coupling effect [31]. The relatively low photothermal ablation efficiency of Au/CMCS NPs is probably due to their less adsorption on the cell membrane (Figures 6(e) and 7(e)). The highest efficiency of the photothermal ablation is observed from the cells treated with Au/CS NPs. There are almost 100% HepG2 cells, and 90% HDF cells were killed after the laser treatment (Figures 6(d) and 7(d)). The CS and CMCS blended coated gold NPs present the promising result: around 96% HepG2 cancer cells were ablated and less than 30% HDF normal cells died (Figures 6(f) and 7(f)). The differences of the Au NPs in the photothermal ablation result from the density of the Au NPs adsorbed on the cell surface. The negatively charged cell surface allows Au/CS NPs to highly accumulate on the cell surface, and high density particles generate extraordinary heat, damaging the HepG2 cells as well as the HDF cells under the laser radiation. Au/(CS+CMCS) NPs bind to the cell surface uniformly and generate suitable heat, which was high enough to kill the cancer cells but not enough to damage all the normal cells. This consists with laser ablation results by using gold nanorod [16]. It was reported that after exposure to continuous red laser, malignant cells require about half the laser energy to be photothermally destroyed than the nonmalignant cells [16].

4. Conclusions

Gold/chitosan nanocomposites were synthesized for the photothermal therapy applications. Au NPs were prepared by the reaction of chloroauric acid with sodium thiosulfate, and they have specific NIR absorption matching the wavelength of laser source. These Au NPs were coated with chitosan or O-carboxymethyl chitosan as well as a blending. These chitosan coatings protect the gold nanoparticles, avoiding irreversible coalescence of the bare Au NPs and improving
Figure 6: Live/dead stain images of the HDF cells treated with different Au NPs after the laser ablation (5 W/cm², 2 min). Figure 7: Live/dead stain images of the HepG2 cells treated with different Au NPs after the laser ablation (5 W/cm², 2 min). (a) control cells with no laser exposure, (b) cells without NPs, (c) cells treated with bare Au NPs, (d) cells treated with Au/CS NPs, (e) cells treated with Au/CMCS NPs, and (f) cells treated with Au/(CS+CMCS) NPs.
their optical stability, making photothermal ablation possible. The surface charge of the Au/chitosan nanocomposites can be modified by adjusting the CS and CMCS components on the gold surface to achieve suitable binding of the Au NPs on the cell surface. The Au/CS nanocomposites show high accumulation on the cell surface and present the highest laser ablation efficiency. The CS and CMCS blended coatings allow Au NPs uniformly binding to the cells, showing higher selectivity between the cancer cells and normal cells during the photothermal ablation. These novel gold/polymer nanocomposites have great potential for photothermal therapy, due to low-dosage particle injection, low-power NIR laser radiation, and quick ablation. More broad clinical relevance can be envisioned, such as the breast cancer treatment, skin cancer treatment, esophageal cancer treatment, and laryngocarcinoma cancer treatment.
