We consider the case of a two-stage serial supply chain system. This supply chain system involves a single vendor who supplies a single buyer with a single product. The vendor’s production rate is assumed finite. In addition, the demand at the buyer is assumed deterministic. In order to coordinate their replenishment policies and jointly optimize their operational costs, the two supply chain partners fully share their relevant information. For this purpose, we develop an integrated inventory replenishment model assuming linear and fixed backorders costs. Then, we use a hybrid geometric-algebraic method to drive the optimal replenishment policy and the minimum supply chain total cost in a closed form.

1. Introduction

Supply chain integration is concerned with functional integration and coordination among the supply chain partners. In an independently managed supply chain, each member in each stage will optimize his own operational costs in a decentralized fashion. Generally, it has been realized that such managerial independence of the supply chain partners may increase the imbalance between demand and supply. Such independence also has been recognized as direct cause of increased costs. This pushed firms towards the full integration of the supply chain resources and the proper coordination of decisions. Researchers report that closer collaboration among the chain partners, increased level of information sharing, and high level of coordination of various decision processes lead to improved customers service and reduced costs. The significant advances in information and communication technologies facilitated the provision and sharing of the business information necessary for efficiency improvement. This, in turn, facilitated the development in the integrated supply chain management.

In recent years, numerous articles in supply chain modeling have addressed the issue of inventory coordination. Banerjee [1] introduced the concept of joint economic lot-sizing problem (JELS) for the case of a single vendor and a single purchaser under the assumption of deterministic demand and lot for lot policy. Since then, numerous articles in supply chain modeling focused on the integrated vendor-buyer inventory models and the joint economic lot-sizing problem [2–4]. An extensive review of integrated models which deal with the interaction between a buyer and vendor is presented in [5]. This review classified the literature dealing with the integrated models into four main classes. The first class represents models which deal with joint economic lot sizing policies. The second class characterizes models which deal with the coordination of inventory by simultaneously determining the order quantity for the buyer and the vendor. The third class is a group of models which deal with integrated problem but do not determine simultaneously the order quantity of the buyer and the vendor. The last class represents models which deal with buyer-vendor coordination subject to marketing considerations. In the following, we provide an overview of selected relevant models.

Goyal and Szendrovits [6] presented a constant lot size model where the lot is produced through a fixed sequence of manufacturing stages, with a single setup and without
interruption at each stage. A one-vendor multibuyer integrat-
ed inventory model was developed in [7] with the objective
of minimizing the vendor’s total annual cost subject to the
maximum cost that the buyer may be prepared to incur. The
single-vendor multibuyers integrated inventory model was
revisited by [8] where he relaxed the constraint of equal-sized
shipments of [9] and suggested that the shipment size should
grow geometrically.

The idea of producing a single product in a multistage
serial production system was extended by [10] to deal with
equal and unequal sized shipments between stages.

Several benefits of coordinating inventory decisions and
sharing related information have been reported in the supply
chain management literature. The investigation by [11] on
the bullwhip effect in supply chains reported that lack of
information sharing can lead to excessive inventory, poor
customer service, lost revenues, unplanned capacities, and
ineffective logistics. They recommend avoiding managerial
independence by integrating various supply chain functions.
They also recommend that firms need to device strategies that
lead to smaller batches or frequent replenishments. Exchange
of substantial quantities of information among the buyer,
supplier, and carrier can increase the efficiency and effective-
ness of the supply chain [12]. Coordinated replenishment can
significantly reduce inventory. Inventory reductions have a
significant impact on supply chain activities. Lower inventory
levels increase operating revenues and reduce the need for
costly facilities [13].

The centralized, coordinated replenishment policy and
the decentralized replenishment policy in a two-echelon,
multi-item supply chain were investigated in the model devel-
oped by [14]. This model determined the optimal common
replenishment cycle for end items and the integer multiples of
the common replenishment cycle for raw materials. Analysis
showed that a centralized, coordinated replenishment policy
was always found to be superior to the decentralized replen-
ishment policy in terms of cost reduction, especially when
major setup costs were high.

Most of these reviewed research articles used differential
calculus to drive the optimal solutions for the integrated pro-
duction inventory models. However, a recent line of research
focused on easier solution methods for the optimization of
these types of systems [15, 16]. For example, [17] introduced
the use of algebraic optimization approach to the EOQ model
with no backorders. Reference [18] used algebraic procedure
to the EPQ formula taking shortages into consideration
within the case of only one backlog cost per unit and time
unit. Reference [19] considered an integrated three-stage
inventory system with backorders. They formulated the prob-
lem to derive the replenishment policies with four-decision-
variables algebraically. Their model was later extended by [20]
to include a fourth stage.

The popularity of the algebraic approach for the optimiza-
tion of production inventory models could be due to the
fact that it requires basic knowledge of simple elementary
mathematics [21]. An exhaustive literature review on the use
of algebraic optimization methods in the development of
production inventory systems is presented in [21]. Interested
readers are referred to the more recent relevant models
presented in [22, 23].

In this paper, we develop a two-stage supply chain inven-
tory model under two types of backordering costs. This model
is an extension of [19], which considered only a single stage
inventory system. The hybrid geometric-algebraic solution
method described in this paper contributes to the trending
research that uses nontraditional derivatives based methods.
The main purpose of this direction of research is developing
useful supply chain models that can be understood and used
without the knowledge of differential calculus [19]. To the best
of the authors’ knowledge, there is no model in the literature
of multistage supply chain modeling that used algebra and
analytical geometry to drive optimal production-inventory
coordination decisions with linear and fixed backorders costs.
The remainder of this paper is organized as follows. The
next section presents the notation and assumptions made for
developing the model. Section 3 describes the development
of the model. A numerical example illustrating the model
application is presented in Section 4. Section 5 contains some
concluding remarks.

2. Notations and Assumptions

2.1. Notations. The following notations are used in develop-
ing the model:

\[ T: \] basic cycle time, cycle time at the end buyer,
\[ S_b: \] setup cost for the buyer,
\[ D: \] the demand rate for the buyer,
\[ S_v: \] setup cost for the vendor,
\[ K_v: \] integer multiplier at vendor,
\[ h_v: \] inventory holding cost per unit time for the buyer,
\[ h_s: \] inventory holding cost per unit time for the vendor,
\[ T_s: \] the stock-out time at the buyer,
\[ \pi: \] backordering cost per unit per unit time (linear) for
\quad \text{the buyer},
\[ \bar{\pi}: \] per unit backorder cost (fixed) for the buyer.

2.2. Assumptions. The following assumptions are made for
the two-stage supply chain model:

(a) a single product is produced by the vendor and trans-
\quad \text{ferred to the buyer;}
(b) replenishment is instantaneous;
(c) production rate and demand rate are deterministic
\quad \text{and uniform;}
(d) a lot produced by the vendor and sent in equal batches
\quad \text{to the buyer;}
(e) complete information sharing policy is adopted;
(f) there are two types of backorders costs.
3. Model Development

We consider a two-stage serial supply chain consisting of a single vendor and a single buyer. This supply chain model is formulated for the integer multiplier inventory replenishment coordination mechanism, where the cycle time at the vendor is an integer multiple of the inventory replenishment cycle time used by the buyer. Shortages are allowed for the end buyer. The buyer’s cost consists of the inventory holding cost, the shortage costs, and the setup cost. Figure 1 shows the inventory pattern for the buyer.

As we can see from Figure 1, the total annual cost for the buyer is given by

$$TC_b = h_b T \frac{D}{2} - T_s D h_b + h_b T_s^2 \frac{D^2}{2T} + \bar{\pi} T \frac{T_s^2 D}{2T} + \pi T \frac{T_s D}{T} + S_b \frac{T}{T}.$$  \hfill (1)

This total annual cost can be rewritten as

$$TC_b = h_b T \frac{D}{2} + T_s D \left( \frac{\pi}{T} - h_b \right) + T_s^2 \frac{D^2}{2T} + \left( \bar{\pi} + h_b \right) T + S_b \frac{T}{T}.$$  \hfill (2)

The total costs at the vendor side are made of three parts. The first part is the cost of carrying inventory of raw materials as they are being converted into finished products during the production portion of the cycle. The second part is the cost carrying inventory of the finished products during the nonproduction portion of the cycle [2]. The third part is the setup cost. Therefore, the total cost for the vendor is

$$TC_v = K_v T \frac{D^2}{2P_v} (h_v + h_v) + (K_v - 1) T \frac{D^2}{2T} h_v + S_v \frac{K_v T}{K_v T}.$$  \hfill (3)

The total cost for the entire supply chain is

$$TC = TC_b + TC_v$$

$$= \frac{T}{2} \left( h_b D - h_b D + K_v \left( D^2 \frac{P_v}{P_v} (h_v + h_v) + D h_v \right) \right) + \frac{1}{T} \left( S_b + S_v \frac{K_v}{K_v} \right) + T_s^2 \frac{D}{2T} \left( \bar{\pi} + h_v \right)$$

$$+ T_s^2 \frac{D}{2T} \left( \bar{\pi} + h_v \right).$$  \hfill (4)

This cost model can be rewritten in the following form:

$$TC = TY + \frac{W}{T} + AT_S^2 + BT_S,$$  \hfill (5)

where

$$Y = \frac{1}{2} \left( h_b D - h_b D + K_v \left( D^2 P_v (h_v + h_v) + D h_v \right) \right),$$

$$W = \left( S_b + S_v \frac{K_v}{K_v} \right),$$

$$A = \frac{D \left( \bar{\pi} + h_v \right)}{2T},$$

$$B = D \left( \bar{\pi} - h_b \right).$$  \hfill (6)

For a fixed replenishment cycle length $T$, (5) can be optimized with respect $T_s$ using the concept of parabola as in [21]:

$$T_S^* = -\frac{B}{2A} = \frac{T h_b - \bar{\pi}}{\bar{\pi} + h_v}.$$  \hfill (7)

Substituting (7) in (5), we get

$$TC = TY + \frac{W}{T} - \frac{D \left( \bar{\pi} - h_b \right)^2}{2T \left( \bar{\pi} + h_v \right)}.$$  \hfill (8)

This can be further rewritten as

$$TC = TY + \frac{W}{T} - \frac{D \pi^2}{2T \left( \bar{\pi} + h_v \right)} + \frac{\pi h_b}{\left( \bar{\pi} + h_v \right)} - \frac{T h_b^2}{2 \left( \bar{\pi} + h_v \right)}.$$  \hfill (9)

Substituting $\bar{Y} = Y - h_b^2 / 2(\bar{\pi} + h_v)$ and $\bar{W} = W - D \pi^2 / 2(\bar{\pi} + h_v)$ in (9), we have

$$TC = T \bar{Y} + \frac{\bar{W}}{T} + \frac{\pi h_b}{\left( \bar{\pi} + h_v \right)}.$$  \hfill (10)

Now, applying the algebraic procedure proposed by [16] and extended by [20], the annual total cost for the entire supply chain in (9) can be represented by factorizing the term $1/T$, and completing the perfect square, one has

$$TC = \frac{1}{T} \left( T^2 \bar{Y} - 2T \sqrt{T \bar{Y} \bar{W}} + \bar{W} + 2T \sqrt{T \bar{Y} \bar{W}} \right) + \frac{\pi h_b}{\left( \bar{\pi} + h_v \right)}.$$  \hfill (11)

After further factorization, we get

$$TC = \frac{1}{T} \left( T \sqrt{\bar{Y} - \bar{W}} \right)^2 + 2T \sqrt{T \bar{Y} \bar{W}} + \frac{\pi h_b}{\left( \bar{\pi} + h_v \right)}.$$  \hfill (12)

It is worthy pointing out that (12) reaches the minimum with respect to $T$ when setting

$$\left( T \sqrt{\bar{Y} - \bar{W}} \right)^2 = 0.$$  \hfill (13)
Hence, the optimal batch size \( T^* \) is

\[
T^* = \sqrt{\frac{W}{Y}}.
\] (14)

Now, for the entire supply chain, the minimum annual total cost is given as

\[
TC = 2\sqrt{YW} + \frac{\pi h_b}{(\bar{a} + h_v)}.
\] (15)

The optimal batch size \( T^* \) is a function of the integer multiplier \( K_v \). We use the method of perfect square to drive the optimal value of this integer multiplier. Substituting for \( Y \) and \( W \) into (15), we get

\[
TC = \sqrt{2\left(\left(K_v a + b\right)\left(c + \frac{d}{K_v}\right)\right)^{1/2}} + \frac{\pi h_b}{(\bar{a} + h_v)},
\] (16)

where \( a = ((D^2/P_v)(h_v + h_u) + Dh_v) \), \( b = h_bD - h_vD - h_v^2/2(\bar{a} + h_u) \), and \( c = S_v - Dr^2/2(\bar{a} + h_v) \), and \( d = S_v \).

Rewriting (16), we get

\[
TC = \sqrt{2\left\{\frac{1}{K_v}\left[K_v\sqrt{ac} - \sqrt{bd}\right]^2 + \left[\sqrt{ad} + \sqrt{bc}\right]^2\right\}^{1/2}}
\] + \frac{\pi h_b}{(\bar{a} + h_v)}.
\] (17)

From (17), setting

\[
[K_v\sqrt{ac} - \sqrt{bd}]^2 = 0,
\] (18)

the optimal value of the integer multiplier \( K_v^* \) is derived as follows:

\[
K_v^* = \sqrt{\frac{bd}{ac}}.
\] (19)

Since the value of \( K_v^* \) is a positive integer, the following condition must be satisfied:

\[
(K_v^*) \cdot (K_v^* - 1) \leq \left(\frac{bd}{ac}\right) \leq (K_v^*) \cdot (K_v^* + 1).
\] (20)

Now, we can substitute \( K_v^* \) from (19) into (14) to find the optimal cycle time size \( T^* \). This optimal value of \( T^* \) is used to get \( T_s^* \) from (7). Also, substituting \( K_v^* \) from (19) into (17) derives the optimal annual total cost in the following closed form:

\[
TC^* = \sqrt{2\left[\sqrt{ad} + \sqrt{bc}\right] + \frac{\pi h_b}{(\bar{a} + h_v)}},
\] (21)

### 4. Numerical Example

In this section, we present a numerical example to illustrate the application of developed solution procedure. The relevant data is shown in Table 1. In addition to this data, it is also assumed that holding cost for the raw material at the vendor is \( h_v = 0.1 \).

By applying the developed hybrid geometric-algebraic method in the previous section, the results of this example are presented in Table 2.

### 5. Conclusion

In this paper, we considered a two-stage supply chain inventory model for coordinating the inventory policies between a vendor and a buyer with full information sharing and planned backorders. We used a hybrid geometric-algebraic method to drive the optimal replenishment policy and the minimum supply chain total cost in a closed form. The described model can be used by the two parties to get benefits of sharing their information and synchronizing their inventory replenishment cycle. The hybrid geometric-algebraic solution method described in this paper contributes to the trending literature that uses nontraditional derivatives based methods.

One clear limitation of the developed model is the assumption of known deterministic demand. Considering a real-world case and relaxing the restrictive model assumptions are good direction for further research. Also, the use of this hybrid geometric-algebraic method for the development of more complex generalized multistage nonserial supply chain inventory models is considered for future research.
