Sensitivity analysis can take structural parameters as variable and achieve the relationship only with one time analysis, which will dramatically reduce the analytical work especially for large scale structures. The comparative study on frequency sensitivity of a transmission tower is actively carried out in this study. The three-dimensional analytical model of a transmission tower is established by using the finite element (FE) method. The sensitivity coefficients to natural frequencies are deduced based on the equation of motion of the tower. In addition, the expression of the frequency sensitivity to Young's modulus, density of material, the cross area of members, torsional stiffness, and bending moment inertia is proposed. A real transmission tower constructed in China is taken as an example to examine the feasibility and reliability of the proposed sensitivity computation approach. An intensive parametric study is conducted in detail in order to compare the sensitivity coefficients of different physical parameters. The work on an example structure indicated that the magnitudes of the sensitivity coefficients of Young's modulus, the density, and the cross area are much larger than those of the torsional stiffness and the bending moment inertia.

1. Introduction

To be a typical spatial steel structure, the transmission tower is widely used as electrical power infrastructures throughout the world. The transmission tower is a high-rise structure with small damping and is prone to strong dynamic excitations, such as earthquakes and wind loadings [1–3]. It is frequently reported across the world that the excessive vibration of a transmission tower under dynamic excitations may induce the structural damage and even failure [4–6]. Therefore, it is necessary to evaluate the structural performance of the transmission tower subjected to external dynamic excitations. Many theoretical and experimental investigations have been carried out during the past two decades for examining the performance of the transmission tower [7, 8]. With regard to the approaches and techniques used for performance evaluation, the transmission tower system is conventionally designed and constructed using appropriate design standards without considering the dynamic optimization effects. Therefore, the common approach does not provide deep insights into the structural transient behaviour under strong dynamic excitations, even though the consideration of dynamic effects may be important. Thus, the vibration-based structural health monitoring (SHM) approaches have been widely utilized in the performance evaluation of civil engineering structures across the world [9–11]. The SHM process needs to develop or improve a mathematical model of a physical system using measurement data to describe the input, output, and noise relationship [12, 13]. Various methods have been developed to improve the quality of the finite element model of a structure using measurement data [14]. Doebling et al. (1998) [15] gave a comprehensive review on SHM. With regard to the different SHM algorithm used, the effects of various physical parameters on the structural responses can be examined in detail to determine the crucial parameters for structural dynamic design and assessment.

For a transmission tower with determined parameters, it is troublesome to attain the relationship between dynamic characteristics and changed parameters by numerous recalculations which will be almost impossible for large
scale structures, while sensitivity analysis as an alternative approach can take structural parameters as variable and achieve the relationship only with one time analysis, which will dramatically reduce the analytical work especially for large scale structures [16]. The sensitivity analysis is a reasonable and powerful tool for investigating the effects of physical parameters on static and dynamic responses. The sensitivity analysis concerns the relationship between parameters available to the structural responses under dynamic excitations. The dependence of response measures, such as displacement, velocity, acceleration, stress, strain, natural frequency, and power function to the structural responses under dynamic excitations. The sensitivity analysis is used to compute the equation of motion of the tower. In addition, the expression of the frequency sensitivity to the Young’s modulus, density of material, the cross area of members, torsional stiffness, and bending moment inertia is proposed. A real transmission tower is taken as the example to investigate the effects of the structural parameters on the natural frequency through the detailed parametric study. An intensive parametric study is conducted to compare the sensitivity coefficients of different physical parameters. A real transmission tower constructed in China is taken as an example to examine the feasibility and reliability of the proposed sensitivity computation approach. The observations made indicate that the magnitudes of the sensitivity coefficients of the Young’s modulus, the density and the cross area are much larger than those of the torsional stiffness and the bending moment inertia. The Young’s modulus, the density and the cross area are important structural parameters affecting the dynamic properties of the transmission tower.

2. Model of Transmission Tower

A transmission tower is a typical truss structure constructed by using steel members, which can be commonly modelled by using beam elements based on the finite element (FE) method [18, 19]. For an Euler-Bernoulli beam element, stiffness matrix of the ith element of a transmission tower in the local coordinate system (LCS) $K_i^e$ is

$$
\begin{array}{c}
\frac{E_i A_i}{l_i} & 0 & \frac{12E_i I_y^i}{l_i^3} & 0 & 0 & \frac{12E_i I_z^i}{l_i^3} \\
0 & \frac{G_i J_z^i}{l_i^3} & 0 & \frac{4E_i I_z^i}{l_i} & 0 & \frac{4E_i I_y^i}{l_i} \\
0 & 0 & \frac{6E_i I_y^i}{l_i^2} & 0 & \frac{6E_i I_y^i}{l_i^2} & 0 \\
0 & 0 & 0 & \frac{E_i A_i}{l_i} & 0 & 0 \\
0 & 0 & 0 & 0 & \frac{12E_i I_z^i}{l_i} & 0 \\
0 & 0 & 0 & 0 & 0 & \frac{12E_i I_z^i}{l_i} \\
0 & 0 & 0 & 0 & 0 & \frac{12E_i I_z^i}{l_i} \\
0 & 0 & 0 & 0 & \frac{6E_i I_y^i}{l_i} & 0 \\
0 & 0 & 0 & 0 & \frac{6E_i I_y^i}{l_i} & 0 \\
0 & 0 & 0 & 0 & \frac{4E_i I_y^i}{l_i}
\end{array}
$$

(1)
The element stiffness matrix in the global coordinate system (GCS) $K_i$ can be expressed as the multiple of the element stiffness matrix $K_i^e$ in the LCS with the coordinate transformation matrix $T_i^e$:

$$K_i = T_i^e T_i^e T_i^e T_i. \quad (2)$$

The mass matrix of the $i$th element of a transmission tower in the LCS $M_i^e$ can be constructed based on lumped mass assumption [20]:

$$M_i^e = \frac{\rho_e A_i l_i}{2} m = \frac{\rho_e A_i l_i}{2} \left[ I_m \ 0 \ 0 \right] \left[ 0 \ 1 \ 0 \right] \left[ 0 \ 0 \ 1 \right] = \left[ I_m \ 0 \ 0 \right], \quad (3)$$

where

$$I_m = \left[ \begin{array}{cccc} 1 & 0 & 0 & 0 \\ 0 & 1 & 0 & 0 \\ 0 & 0 & 1 & 0 \\ 0 & 0 & 0 & 1 \end{array} \right]. \quad (4)$$

The element mass matrix of the $i$th structural member in the GCS $M_i$ can be expressed as

$$M_i = T_i^e T_i^e M_i^e T_i^e. \quad (5)$$

The global mass matrix $M$ and stiffness matrix $K$ of the transmission tower can be expressed, respectively, as follows:

$$M = \sum_{i=1}^{\pi} T_i^e T_i^e M_i^e T_i, \quad (6)$$

$$K = \sum_{i=1}^{\pi} T_i^e K_i^e T_i, \quad (7)$$

where $\pi$ is the number of elements of a transmission tower; $T_i$ is the freedom transform matrix from the LCS to the GCS.

### 3. Frequency Sensitivity Analysis

#### 3.1. Differential Sensitivity Analysis

The performance assessment of complex structures to satisfy the dynamic response restrictions is commonly hampered by the computational cost of dynamic analysis. There is a fundamental requirement for the information relating changes in the dynamic response quantities to changes in the structural parameters as well as a need for rapid reanalysis in structural performance evaluation. The sensitivity analysis of dynamic characteristics on structural parameters is very important and widely accepted in the structural design, optimization, and evaluation. Sensitivity coefficients are defined as the rate of change of a particular response quantity $R$ with respect to a change in a structural parameter $x$. Sensitivity coefficients can be either evaluated as absolute, relative, or normalized relative values. Relative values are independent of the units of the parameter value while, in addition, normalized relative parameters are also normalized with respect to the response value.

A differential sensitivity coefficient is the slope of the response $R_j$ with respect to parameter $x_i$, computed at a given state of the parameter. When this differential is computed for all selected responses with respect to the selected parameters, the element of the sensitivity matrix $S$ is obtained:

$$S_{ji} = \frac{\partial R_j}{\partial x_i} \left( j = 1, 2, \ldots, \pi; \ i = 1, 2, \ldots, m \right). \quad (7)$$

In which $\pi$ is the number of the responses; $m$ is the number of the structural parameter. The absolute sensitivity coefficient $S_{ji}$ is the $(j, i)$th element in the sensitivity matrix $S$.

The absolute sensitivity coefficients are computed by using the units of the response and parameter value. If sensitivities for different types of parameters are to be compared, the relative sensitivities can be adopted:

$$S' = S \cdot P, \quad (8)$$

where $P$ is a diagonal, square matrix holding the parameter values. The relative sensitivity coefficient is given by

$$S'_{ji} = \frac{\partial R_j}{\partial x_i} \left( j = 1, 2, \ldots, \pi; \ i = 1, 2, \ldots, m \right). \quad (9)$$

Relative sensitivities can be normalized with respect to the response value

$$S'' = S' \cdot R = S \cdot P \cdot R, \quad (10)$$

where $R$ is a diagonal, square matrix holding the response values. The normalized relative sensitivity coefficient is given by

$$S''_{ji} = R_j^{-1} \frac{\partial R_j}{\partial x_i} \left( j = 1, 2, \ldots, \pi; \ i = 1, 2, \ldots, m \right). \quad (11)$$

#### 3.2. Frequency Sensitivity

The eigenvalue equation of a MDOF transmission tower can be expressed as [21, 22]

$$\left( K - \omega^2 \right) \varphi = \mathbf{0}, \quad (12)$$

where $M$, $K$ and $\varphi$ are the mass matrix, stiffness matrix and modal vector of the transmission tower respectively. The eigenvalue equation of the $r$th mode vibration is

$$\left( K - \omega_r^2 \right) \varphi_r = \mathbf{0}. \quad (13)$$

The mass matrix, stiffness matrix, and modal vector are the function of physical parameters. Thus, the first derivative of (13) to the parametric $x_i$ of the $r$th structural member for the $r$th mode vibration results in

$$\frac{\partial K}{\partial x_i} \varphi_r + \left( K - \omega_r^2 M \right) \varphi_r = \mathbf{0}, \quad (14)$$

in which $\omega_r$ and $\varphi_r$ are the $r$th circular frequency and modal vector of the system. Since the mass and stiffness matrices are a symmetric matrix, there exists

$$\varphi_r^T \left( K - \omega_r^2 M \right) \varphi_r = \mathbf{0}. \quad (15)$$
To pre-multiply the vector $\varphi^T$ to (14) will yield
\[
\frac{\partial \omega^2}{\partial x_i} = \frac{\varphi^T \partial K / \partial x_i - \omega^2 (\partial M / \partial x_i) \varphi}{\varphi^T M \varphi},
\] (16)
The relationship between the circular frequency $\omega_r$ and natural frequency $f_r$ of the $r$th vibration mode can be written as
\[
\frac{\partial \omega^2}{\partial x_i} = 2 \omega_r \frac{\partial \omega_r}{\partial x_i},
\] (17)
\[
\frac{\partial \omega}{\partial x_i} = 2 \pi \frac{\partial f_r}{\partial x_i},
\] (18)
The sensitivity of the frequency to the $i$th structural parameter $x_i$ is
\[
\frac{\partial f_r}{\partial x_i} = \frac{1}{8 \pi^2 f_r}, \varphi^T \Sigma_{i=1}^{ne} \left( \partial K_{ij} / \partial x_i \right) - 4 \pi^2 f_r^2 \Sigma_{i=1}^{ne} \left( \partial M_{ij} / \partial x_i \right) \varphi, \frac{\varphi^T M \varphi}{\varphi^T M \varphi},
\] (19)
Equation (18) provides a way to calculate the sensitivity of the $r$th natural frequency to the change in the $i$th structural parameter $x_i$. Assuming that the transmission tower is linear and the change in natural frequency due to the change of structural parameter is small, the change in the $r$th natural frequency $\Delta f_r$, due to the variations of the structural parameter $\Delta x_i$, can be expressed as
\[
\Delta f_r = \frac{\partial f_r}{\partial x_i} \Delta x_i.
\] (20)
3.3. Frequency Sensitivity of Structural Parameter. The sensitivity of the $r$th natural frequency to the structural parameter $x_i$ can be rewritten by using the element stiffness matrix $K_{ij}$ and mass matrix $M_{ij}$ of the $i$th element in the GCS:
\[
\frac{\partial f_r}{\partial x_i} = \frac{1}{8 \pi^2 f_r}, \varphi^T \Sigma_{i=1}^{ne} \left( \partial K_{ij} / \partial x_i \right) - 4 \pi^2 f_r^2 \Sigma_{i=1}^{ne} \left( \partial M_{ij} / \partial x_i \right) \varphi,$
\] (21)
in which $ne$ denotes the total number of the members of the transmission tower. The sensitivity of the $r$th natural frequency to the Young’s modulus of the $i$th structural element $E_i$ is given by
\[
\frac{\partial f_r}{\partial E_i} = \frac{1}{8 \pi^2 f_r}, \varphi^T \Sigma_{i=1}^{ne} \left( \partial K_{ij} / \partial E_i \right) \varphi,$
\] (22)
where
\[
\frac{\partial K_{ij}}{\partial E_i} = \frac{\partial K_{ij}}{\partial (E_i A_i)} \frac{\partial (E_i A_i)}{\partial E_i} + \frac{\partial K_{ij}}{\partial (E_i I_x)} \frac{\partial (E_i I_x)}{\partial E_i} + \frac{\partial K_{ij}}{\partial (E_i I_y)} \frac{\partial (E_i I_y)}{\partial E_i} + \frac{\partial K_{ij}}{\partial (E_i I_z)} \frac{\partial (E_i I_z)}{\partial E_i}.
\] (23)
The sensitivity of the $r$th natural frequency to the density of the $i$th structural element $\rho_i$ is
\[
\frac{\partial f_r}{\partial \rho_i} = \frac{f_r}{2}, \varphi^T \Sigma_{i=1}^{ne} \left( \partial M_{ij} / \partial \rho_i \right) \varphi,$
\] (24)
Substituting (3) into (23) yields
\[
\frac{\partial f_r}{\partial \rho_i} = \frac{f_r}{4}, \varphi^T \Sigma_{i=1}^{ne} \left( \partial M_{ij} / \partial \rho_i \right) \varphi,$
\] (25)
where $A_i$ and $L_i$ are the cross area and the length of the $i$th structural element, respectively. The sensitivity of the $r$th natural frequency to the cross area of the $i$th structural element $A_i$ is
\[
\frac{\partial f_r}{\partial A_i} = \frac{1}{8 \pi^2 f_r}, \varphi^T \Sigma_{i=1}^{ne} \left( \partial K_{ij} / \partial A_i \right) - 4 \pi^2 f_r^2 \Sigma_{i=1}^{ne} \left( \partial M_{ij} / \partial A_i \right) \varphi,$
\] (26)
(27)
(28)
(29)
The sensitivity of the $r$th natural frequency to the Poisson’s ratio of the $i$th structural element $\mu_i$ is
\[
\frac{\partial f_r}{\partial \mu_i} = \frac{1}{8 \pi^2 f_r}, \varphi^T \Sigma_{i=1}^{ne} \left( \partial K_{ij} / \partial \mu_i \right) \varphi,$
\] (30)
where
\[
\frac{\partial K_{ij}}{\partial \mu_i} = \frac{I_i}{1 + \mu_i}, \varphi^T \Sigma_{i=1}^{ne} \left( \partial K_{ij} / \partial \mu_i \right) \varphi,$
\] (31)
4. Case Study

4.1. Description of an Example Transmission Tower. To examine the frequency sensitivity based on the proposed approach, a real transmission tower constructed in China is taken as the example structure. Figure 1 shows the elevation of a large transmission tower used for electric power transfer. The transmission tower with a height of 84.5 m is located in the southern coastal area in China. The structural members used in the transmission tower are made of Q235 steel with a yielding stress of 235 MPa. Young's modulus of the steel is $2.01 \times 10^3 \, \text{N/m}^2$ and the density is 7800 $\text{kg/m}^3$. The vertical major members, the skew members, the cross arms, and the platform of the tower are formed as a spatial truss tower as shown in Figures 2(a), 2(b), and 2(c), respectively. Six platforms are connected to the vertical major members to form the tower body and the skew members are incorporated to increase the vertical and lateral stiffness of the entire tower. Two cross arms are constructed on top of the tower body for the connection of the transmission lines. A three-dimensional FE model is constructed based on the FE method with the aids of the commercial package.

A three-dimensional finite element model is established for the steel transmission tower using a commercial computer package. The model has a total of 1324 3D beam elements and 488 nodes with 6 degrees of freedom at each node. All the joints in the finite element model are assumed to be rigid. The movement of all the supports in the three orthogonal directions is restricted. For the sake of convenience in the subsequent discussion, the beam elements in each component of the transmission tower are numbered differently. The beam elements in the vertical major members are numbered from 1 to 80 (denote zc), the elements in the platforms are numbered from 81 to 408 (denote pt), the elements in the skew members are counted from 409 to 772 (denote xg), the elements in the lower cross arm are counted from 773 to 1072 (denote hd1), and the elements in the upper cross arm are counted from 1073 to 1324 (denote hd2). The number of vertical major members is only 6% of the total number of elements used in the structure while the number of skew members is 24.7% of the total number of elements used in the structure. Except that the vertical major members are of hollow circular section, all the other members are of angle section.

4.2. Dynamic Characteristics of the Transmission Tower. The dynamic characteristics analysis is conducted based on the established finite element model of the steel transmission tower. The first eight natural frequencies and vibration modes of the tower are depicted in Table 1 and Figure 3, respectively. The first natural frequencies of the transmission tower for the out-of-plane and in-plane vibration are 1.736 Hz and 1.759 Hz, respectively. It is seen that the first and second vibration modes are the global vibration mode in the $x$ direction and $y$ direction, respectively. The third vibration mode is a global torsional vibration mode in the $x$-$y$ plane due to the tower rotation. The fourth to sixth vibration modes are the high order translational and torsional vibration modes of the tower. The first eight natural frequencies computed indicate that the natural frequencies of the structure are not closely spaced. The dynamic responses of the first three mode shapes are the major parts of the entire dynamic responses of the transmission tower.

4.3. Frequency Sensitivity of the Transmission Tower. Figure 4 shows the sensitivities of the first eight natural frequencies to Young's modulus of each member. It is seen from the first two figures that the first two natural frequencies are more sensitive to Young's modulus change of members in the vertical major members (zc) than other members. The curves in the third figure indicate that the sensitivity coefficients of the first torsional frequency of the skew members are much larger than those of the other members. All the higher natural frequencies of the global vibration are more sensitive to Young's modulus change of both vertical major members and the skew members. This is consistent with the structural configuration and the modes of vibration; the first two translational modes of vibration are mainly due to the deformation of the vertical major members and the first torsional mode is due to the deformation of the skew members. However, the higher modes of vibration are mainly due to the movement combination of both vertical major members and the skew members. The seventh vibration mode is the local vibration of the platform number 1 and thereby the seventh natural frequency is clearly sensitive to Young's modulus of the platform number 1. To compare the magnitude of the sensitivity coefficients in Figure 4, one can find that Young's modulus of the vertical major members plays an important role in the first two vibration modes in comparison with all the other vibration modes. The sensitivity coefficients of the skew members are slightly smaller than those of the vertical major members.

Displayed in Figure 5 is the sensitivity of the first eight natural frequencies to the density of the material. It is well known that the natural frequencies decrease with

the increasing material density. Therefore, it is indicated from Figure 5 that the sensitivity coefficients are negative. It is seen that the sensitivity coefficients of the natural frequencies to the density are quite different to those of Young’s modulus. The first two figures demonstrate that the first two natural frequencies are more sensitive to the density change of members in the vertical major members (zc) and cross arms. However, the density sensitivity coefficients of the skew members and platforms are much smaller. The curves in the third figure indicate that the sensitivity coefficients of the first torsional frequency of the two cross arms are much larger than those of the other members. This is because the third mode is the torsional vibration of the two cross arms. The second-order translational frequencies of both the out-of-plane vibration and in-plane vibration, namely, the fourth and fifth frequencies, are dominantly sensitive to the density change of the vertical major members. Similar observations can be made from the density sensitivity of the second order torsional modes (e.g., the sixth mode) because this mode is the torsional vibration of the tower body. Regarding
the higher order translational modes, the density of skew members may have slight effects on the sensitivity coefficients as shown in the eighth figures in Figure 5.

Figure 6 indicates the sensitivities of the first eight natural frequencies to the cross area of each member. It is clear that the sensitivity coefficients of the cross area are quite different to those of Young's modulus and density. The increase of member cross area does not always cause the increment of the structural natural frequencies. It is seen from the first two figures that the first two natural frequencies are more sensitive to the cross area change of the vertical major members than other members. As far as the first two natural frequencies are concerned, the increase in cross area of most of the vertical major members may induce the increment of the natural frequencies. On the contrary, the increase in the member cross areas of the two cross arms may lead to the increase of the global mass instead of the stiffness. Therefore, the structural natural frequencies may decrease to some extents. As displayed in the third figure, the skew members can be strengthened by increasing the cross areas and the third natural frequency, corresponding to the first order torsional mode, can be increased. Similar observations can be found from the sensitivity coefficients of the other higher natural frequencies. It is seen that the sensitivity coefficients of Young's modulus and the cross area are similar to great extents. The stiffness matrix of the $i^{th}$ element of a transmission tower in the local coordinate system $\mathbf{K}_i$ is expressed in (1). It can be found that both Young's modulus $E$ and cross area $A$ have an important contribution to the axial stiffness $EA/l$ of a single member. In addition, Young's modulus also makes the contribution to the member bending stiffness $EI/l^3$. Therefore, the comparison between
Figures 4 and 6 indicate that the magnitudes of the sensitivity coefficients of Young's modulus are slightly larger than those of the cross area. Sensitivity of the first eight natural frequencies to the torsional stiffness $I_x$ is displayed in Figure 7. It is seen from the third figure that the sensitivity coefficients of the third frequency to the torsional stiffness are much larger than those of the all the other frequencies. Therefore, the frequency sensitivity coefficients to the torsional stiffness are substantially smaller than those of Young's modulus, the density, and the cross area. The torsional stiffness of structural members may have a certain level of effects on the torsional
vibration modes of the transmission tower. The sensitivity of first eight natural frequencies to the bending moment of inertia $I_y$ and $I_z$ are indicated in Figures 8 and 9, respectively. Similarly, the frequency sensitivity coefficients to the bending moment stiffness are also remarkably smaller than those of Young's modulus, the density, and the cross area. It is found that the sensitivity coefficients of the major vertical members are much larger than those of the other members for the first five natural frequencies. This observation means that the effects of the bending moment inertia of the major vertical
5. Concluding Remarks

The feasibility of evaluating the parametric effects of a transmission tower based on the frequency sensitivity analysis is actively carried out in this study. The 3D analytical model of a transmission tower is first constructed by using the FE method. The differential sensitivity analysis approach is presented based on the differential sensitivity coefficient, the absolute sensitivity coefficient, and the relative sensitivity coefficient, respectively. The sensitivity coefficients to natural frequencies are deduced based on the equation of motion of the tower. In addition, the expression of the frequency

members on structural modal properties are more obvious in comparison with other members.
sensitivity to Young’s modulus, density of material, the cross area of members, torsional stiffness, and bending moment inertia is proposed. A real transmission tower-line system is taken as the example to investigate the effects of the structural parameters on the natural frequency through the detailed parametric study.

The observations made demonstrate that Young’s modulus of the vertical major members plays an important role in the first two vibration modes in comparison with all the other vibration modes. The sensitivity coefficients of the skew members are slightly smaller than those of the vertical major members. The sensitivity coefficients of the natural frequencies to the density are different to those of Young’s modulus because the natural frequencies decrease with the increasing material density. The sensitivity coefficients of the cross area are quite different to those of Young’s modulus and
density. The increase of member cross area does not always cause the increment of the structural natural frequencies. The frequency sensitivity coefficients to the torsional stiffness and the bending moment stiffness are substantially smaller than those of Young's modulus, the density, and the cross area. To compare the magnitudes of the sensitivity coefficients, one can find that Young's modulus, the density, and the cross area are more important structural parameters in assessing the dynamic performance of the transmission tower.
