The role of resident cells during the lipopolysaccharide (LPS)-induced neutrophil recruitment into rat air pouches was investigated. In this model, LPS (Escherichia coli, O55: B5 strain; 2–2000 ng) induced a dose- and time-dependent neutrophil recruitment accompanied by the generation of a tumour necrosis factor-α (TNFα)-like activity. Dexamethasone (0.05–5 μg) and cycloheximide (6 ng), injected 2 h before LPS into the pouches, inhibited the neutrophil recruitment and the generation of the TNFα-like activity, while the H1-receptor antagonist mepyramine (1 and 4 mg/kg, i.p., 0.5 h before LPS) and the PAF-receptor antagonist WEB 2170 (0.05 and 1 mg/kg, i.p., 0.5 h before LPS) had no effect. Purified alveolar macrophages (AM) were used to replenish the pouches of cycloheximide-treated recipient rats. AM provided by PBS-treated animals led to the recovery of the LPS-induced neutrophil recruitment and of the TNFα-like formation contrasting with those from cycloheximide-treated animals (1 mg/kg, i.p.). When delivered in situ, liposome-encapsulated clodronate, a macrophage depletor, significantly impairs both the LPS-induced neutrophil recruitment and the TNFα-like activity. An anti-murine TNFα polyclonal antibody (0.5 h before LPS) was also effective. These results emphasize the pivotal role of macrophages for LPS-induced neutrophil recruitment via the formation of TNFα.

Key words: Rat air pouch, Lipopolysaccharide, Neutrophil recruitment, Macrophage, Tumour necrosis factor-α

Introduction

Leukocyte recruitment1-2 and the formation of pro-inflammatory mediators, including different cytokines, are the hallmark of an inflammatory response. The latter is characterized by vasodilatation, rapidly followed by neutrophil adhesion to endothelium and migration into the perivascular connective tissue.

In vitro studies have shown that the bacterial endotoxin (lipopolysaccharide, LPS) is not by itself a chemotactic factor,3 even though LPS may interact with neutrophils via CD14 and the LPS-binding protein (LBP) to express CR3 activity which mediates neutrophil adhesion.4,5 In fact, local cell targets seem to be more relevant in vivo and in particular, resident macrophages are believed to play a pivotal role in the recognition and the transduction of the effects of LPS (for review, see Manthey and Vogel6) since they produce the chemotactic mediators IL-1α and β, TNFα, IL-8 and MIP-1 and 2 as well as LTB4 and PAF. Furthermore, LPS elicits a selective and transient cycloheximide-dependent collagenase synthesis by macrophages, providing thus another potential tissue damaging factor.7

Initially described as a potent inflammatory cytokine derived from LPS-activated macrophages, TNFα may also account for neutropenia,9 neutrophilia8,9 and neutrophil recruitment10-12 and activation.13,14 TNFα also induces the expression of cell surface molecules, leading to adherence on endothelial cells.15 As an early cytokine, TNFα is released extracellularly within 15 min after its gene transcription upon exposure to inflammatory stimuli.16 Its broad spectrum of activities and the amounts produced by macrophages stimulated by various products (up to 2% of their total biosynthesis) suggest that TNFα is an important mediator of LPS-induced inflammatory response.17 Glucocorticoids such as dexamethasone inhibit the production of circulating TNFα in mice, rats18 and guinea-pigs19 treated with LPS. Dexamethasone also alters the phagocytic functions of
macrophages in vitro$^{20}$ and contributes to protect rat macrophages against LPS-induced TNFα production in vitro, even though less so in vivo.$^{21}$

The cutaneous air pouch provides a virtual cavity which can be tailored as a migration chamber covered innerly with a lining membrane, the facsimile synovium.$^{22}$ Since the walls of the pouch are formed by macrophages and fibroblasts and a few mastocytes, we took advantage of this model to study the mode of action of LPS. Because of the potential damage engendered by the neutrophil towards connective tissue,$^{23}$ we investigated the dependency of LPS-induced neutrophil emigration upon resident cells and bring evidence that macrophages and TNFα are respectively the target and the mediator of neutrophil recruitment following LPS injection into rat air pouches.

Materials and Methods

Animals

Brown-Norway rats (200–250 g) (Iffa Credo, France) were allowed to take food and drink ad libitum at room temperature.

Rat air pouch

The air pouch was induced according to Edwards et al.$^{22}$ At day 0, rats were anaesthetized with ketamine (50 mg/kg, i.m.) and their dorsum was thoroughly shaved and gently disinfected with ethanol 70%. Syringes and needles were one-purpose material. Twenty ml of sterile air taken under a laminar flux hood were injected subcutaneously with a gauge 26G

Neutrophil migration assessment

At various times (2 h, 24 h, 48 h and 96 h) after LPS injection, animals were killed with an overdose of sodium penthiobarbitone. Four ml of heparinized PBS solution (5 IU/ml) were injected into the pouch in order to wash the cavity by a gentle massage. The washing solution which was recovered at over 95% was collected into 6 ml-polypropylene round bottom tubes (Falcon® 2063, sterile/gamma irradiated) stored on an ice bath.

Injection of the mastocyte degranulating agent compound 48/80, under 1 ml (250 µg/ml) into the rat air pouch followed the same procedures. This concentration was chosen for its ability to induce granulocyte infiltration in the mouse skin.$^{24}$

Leukocyte and differential counts were performed with a cell counter (Coulter®) and a Cytospin (Hettich Universal®), respectively, and allowed to calculate the total number of leukocyte neutrophils recovered.

One ml aliquots prepared from the pouch washing were centrifuged (400 g, 10 min at 4°C), pellets and aliquoted supernatants being kept at −40°C until further analysis.

TNFα assay

TNFα production was determined directly in the supernatant using the TNFα sensitive cell line WEHI-164. Cells were plated out in 96-well plates (8 × 10^4 cells/50 µl/well) and the samples (50 µl/well) or the human recombinant TNFα (hr-TNFα) standards (1–10^6 U/ml hr-TNFα, 50 µl/well) were added. After 24 h incubation (37°C, 7.5% CO₂), MTT (tetrazolium salt, Sigma, USA) was added (0.125 mg/well). After an incubation of 4 h, the cells were lysed with buffer (20% sodium dodecyl sulphate (SDS) in 50% N,N-dimethylformamide (DMF), pH 4.7, 100 µl/well) for 18 h. The difference of absorbances measured at 550 nm and 630 nm with an ELISA reader (Dynatech MR5000) allowed to evaluate the TNFα-like activity.

Modulation of neutrophil recruitment

In some experiments, cycloheximide (6 ng/ml) or dexamethasone (0.5–5 µg/ml) were injected into the pouch 2 h before LPS (200 ng/ml) under a volume of 1 ml. In other experiments, animals received mepyramine (1–4 mg/kg) i.p. 30–45 min before LPS was injected into the pouch.

An anti-murine TNFα immunoglobulin preparation was prepared as follows. Female HY/CR rabbits (2500 g; Charles River, St Aubin les Elbeouefs, France) were immunized at 2 weeks intervals by three injections of reduced murine rTNFα (Immungenex, Los Angeles, CA, USA) emulsified in adjuvant (Hunter Titermax; CytRx Co., Norcross, Germany): the first one with 50 µg, the second and the third with 25 µg. The animals were bled 2 weeks after the last injec-
tion, and total immunoglobulins were obtained after precipitation with 40% saturation of ammonium sulphate. Purified murine polyclonal anti-TNFα (2.5 mg/ml) was administered into the rat air pouches in a volume of 0.7 ml, 0.5 h before LPS. Control animals were treated under same conditions with the same amounts of preimmune immunoglobulins.

**Macroage replenishment**

Rats were anaesthetized (sodium pentobarbitone, 60 mg/kg, i.p.), the trachea was cannulated and broncho-alveolar lavages (BAL) with sterile saline under a volume of 6 ml were performed. This procedure was repeated until a final volume of 36 ml was obtained in a 50 ml-polypropylene graduated conical tube (Falcon© 2098, Blue Max, sterile/gamma irradiated) on ice bath. Immediately after centrifugation (400 g, 5 min at 4°C), the cell suspension underwent an hypotonic lysis with sterile water to remove remaining erythrocytes. Then, cells were counted (Counter Coulter©) and the suspension was diluted to a final concentration of 10⁶ and 10⁴ cells per ml. Purity and viability were assessed by differential count and blue trypan dye exclusion, respectively.

In other experiments, rats were treated with cycloheximide i.p. (1 mg/kg, 0.5 ml). Control animals received similar volumes of saline. After 2 h, the animals were sacrificed with an overdose of pentobarbitone and both groups underwent the same procedure to purify the alveolar macrophages.

**Liposome preparation and experimental design**

Multilamellar liposomes were prepared according to Van Rooijen and Van Nieuwmegen. In brief, 75 mg dipalmitoylphosphatidylcholine and 11 mg cholesterol were dissolved in chloroform in a round bottom flask. The thin film that formed on the walls after rotary evaporation at 45°C was dispersed by gentle shaking for 10 min in 10 ml of PBS (pH 7.4), in order to prepare empty liposomes, and in 10 ml of a solution of 2 g clodronate (dichloromethylene diphosphonate or Cl₂MDP) in PBS, in order to prepare liposomes with encapsulated Cl₂MDP. The preparation was kept for 2 h at room temperature and sonicated four times for 5 min at 45°C in a waterbath (50 Hz) and kept at room temperature for a further 2 h. Then, liposomes were filtered through 1.2-μm Minisart NML filters (disposable syringe holders, sterile, pyrogenfree, hydrophilic, Sartorius, Germany) centrifuged at 100,000 g to 0.5 h, finally resuspended in 5 ml PBS and kept at 4°C.

Rats with 7-day-old air pouches were anaesthetized and injected into this preformed cavity with either 0.3 ml liposome-encapsulated clodronate or 0.3 ml liposome-encapsulated PBS (empty liposome) for 96 h before LPS stimulation as previously described.

In order to overcome the cell counter inability to differentiate the remaining injected liposomes and the LPS-recruited cells, 100 µl aliquots of pouch washing were allowed to stretch on glass slides by cytocentrifugation. After a Diff-Quik® staining, the slides were observed under light microscope at magnification ×1000. A differential leukocyte count was performed (neutrophil, eosinophil, mononuclear cell) taking account of the total fields observed. Thus, the data was expressed as the number of neutrophils per field.

**Materials**

Lipopolysaccharide from *Escherichia coli* strain O55: B5 was purchased from Difco (Detroit, MI, USA); heparin from Choay (Paris, France); ketamine hydrochloride (KETALAR©) stored at 4°C as a 100 mg/ml stock solution was from Parke-Davis (Courbevoie, France); sodium pentobarbitone was from Sanofi Santé Animale (Lbourne, France); compound 48/80, bovine serum albumin, tetrzolium salt (MIT), the histamine-receptor antagonist HI pyrilamine maleate (mepyramine), dexamethasone phosphate, chloroform, dipalmitoylphosphatidylcholine and cholesterol were from Sigma (St Louis, MO, USA); PAF-receptor antagonist WEB 2170 was a kind gift of Boehringer Ingelheim (Germany), cycloheximide was from Merck (Darmstadt, Germany); Diff-Quik® kit was purchased from Baxter S.A. (Mairepas, France), clodronate disodium salt (dichloromethylene diphosphonate, Cl₂MDP) was a kind gift of Boehringer Mannheim GmbH (Germany); murine recombinant TNFα was purchased from Immungenex (Los Angeles, CA, USA); human recombinant TNFα was a kind gift of Dr G. R. Adolf (Wien, Austria); WEHI-164 cells were a kind gift of Dr I. L. Bonta (Rotterdam, The Netherlands).

**Data analysis**

Experimental value are given as mean ± SEM. Statistical significance of differences between two means of data were evaluated by a Student’s t-test for unpaired observations and P-values less than 0.05 were considered to be significant.
Results

Dose-effect relationship induced by LPS compared with compound 48/80

LPS (2–2000 ng, 2 h) induced a dose-dependent leukocyte recruitment (Fig. 1a) which was predominantly formed by neutrophils (LPS: 67 ± 5.7% vs. control: 14.6 ± 7.6%, *P* < 0.001, *n* = 5–7) (Fig. 1b). The threshold dose of LPS for inducing a significant leukocyte infiltration was 20 ng (*P* < 0.05, *n* = 7) which correlated with the enhancement of the neutrophil population at this dose (*P* < 0.01, *n* = 7). Since leukocyte and neutrophil infiltration plateaued at 200 ng, this dose was chosen for further experiments. By contrast, compound 48/80 (250 μg, 2 h) failed to elicit leukocyte infiltration, compared with the vehicle.

Time-course of leukocyte and neutrophil recruitment induced by LPS

Leukocyte recruitment by LPS (200 ng) peaked at 2 h and 24 h (Table 1) (*P* < 0.01, *n* = 7) and was over at 48–96 h. Since at 2 h cell infiltration was predominantly constituted by neutrophils (Table 1) (*P* < 0.01, *n* = 7), this time point was chosen for subsequent studies.

Detection of TNFα-like activity in supernatants of pouch

Injected at the dose of 200 ng (2 h), LPS induced the generation of a significant TNFα-like activity detected in the pouch washings (*P* < 0.01, *n* = 5–9) under conditions where compound 48/80 (250 μg/ml, 2 h) failed to do so (Fig. 2).

Interference of dexamethasone with LPS-induced neutrophil recruitment and TNFα-like activity, failure of mepyramine and WEB 2170

Injected 2 h before LPS, dexamethasone (50–5000 ng) inhibited dose-dependently the LPS-induced recruitment of neutrophils (*P* < 0.01 for the dose of 5000 ng, *n* = 7) (Fig. 3). Accordingly, the threshold for inhibition was between 1000 and 2500 ng. By contrast, the H1-receptor antagonist mepyramine (1 and 4 mg/kg, i.p., 0.5 h before LPS) and the PAF-receptor antagonist WEB 2170 (0.05 and 1 mg/kg, i.p., 0.5 h before LPS) failed to interfere with the LPS-induced recruitment of neutrophils (Tables 2 and 3).

Injected 2 h before LPS, dexamethasone (5000 ng) also inhibited the generation of TNFα-like activity (*P* < 0.05, *n* = 6) (Fig. 3, inset).

| Table 1. Time-course of the LPS-induced leukocyte and neutrophil recruitment into rat air pouches. Leukocyte and neutrophil recruitment was evaluated at different time-points (2 h, 24 h, 48 h and 96 h) for the dose of 200 ng of LPS injected into the air pouches under a volume of 1 ml. Results are expressed as mean ± SEM for *n* = 5–7 experiments (*PP* < 0.01) |

Interference of cycloheximide with LPS-induced neutrophil recruitment and generation of TNF-α-like activity

Injected into the pouch at 6 ng, 2 h before 200 ng of LPS, cycloheximide inhibited significantly the LPS-induced neutrophil recruitment (Fig. 4) (P < 0.01, n = 5), but it was inactive, when injected together with LPS (P > 0.05, n = 5). Similarly, cycloheximide interfered with the TNF-α-like activity generated by LPS (Fig. 4, inset) (P < 0.05, n = 5).

Replenishment of cycloheximide-treated pouches with alveolar macrophage (AM) restores the LPS-induced recruitment of neutrophils and the accompanying generation of TNF-α-like activity

Alveolar macrophages (AM) (purity: 90% viability: 95%) were adjusted to a final concentration...
of $10^6$ and $10^4$ cells per ml and injected into the air pouch previously treated with cycloheximide (6 ng per pouch, 2 h before). This replenishment restored significantly the LPS-induced neutrophil recruitment when compared with cycloheximide-treated pouches or with PBS stimulation (Fig. 5). In addition, replenishment with $10^4$ AM per ml from cycloheximide-treated animals failed to support the LPS-induced neutrophil recruitment (Fig. 6), contrasting to AM from control animals ($P < 0.001$ for neutrophils, $n = 6$).

Replenishment with $10^6$ AM/ml also restored the generation by LPS of TNF-α-like activity in the pouch. Indeed, the replenished animals generated $13.02 \pm 3$ ng/ml of TNF-α-like activity upon LPS injection, whereas cycloheximide-treated animals generated $2.4 \pm 2.4$ ng/ml ($n = 5; P < 0.05$) (Fig. 5, inset). By contrast, replenishment with $10^4$ AM/ml generated $4.06 \pm 0.4$ ng/ml of TNF-α-like activity, a value not significant different from that obtained with AM from cycloheximide-treated animals (Fig. 6, inset).

Interference of liposome-encapsulated clodronate with LPS-induced neutrophil recruitment and generation of TNF-α-like activity in rat air pouches

Liposome-encapsulated clodronate, injected into the rat air pouches (300 μl, 96 h before LPS), produced a marked inhibition of LPS-induced neutrophil emigration (Fig. 7) and generation of TNF-α-like activity (Fig. 7, inset) in rat air pouches, when compared with empty liposomes (control: $57.1 \pm 11.9$ neutrophils per field; $20.6 \pm 13$ ng/ml TNF-α-like activity; treated: $10.3 \pm 1.7$ neutrophils per field; $2.4 \pm 0.5$ ng/ml TNF-α-like activity; $n = 5–6$, $P < 0.01$ and $P < 0.01$ respectively).

**FIG. 5.** Effects of replenishment with alveolar macrophages on LPS-induced recruitment of neutrophils and TNF-α-like activity in rat air pouches. For the recruitment, air pouches were pretreated with 6 ng of cycloheximide for 2 h, then replenished with $10^6$ macrophages for four animals or with $10^4$ macrophages for six animals under a volume of 1 ml for 0.5 h, then stimulated with LPS (200 ng) or PBS for 2 h under a volume of 1 ml. Results are expressed as mean ± SEM of total number of cells. For the TNF-α-like activity (inset), the same conditions were used and results are expressed as mean ± SEM of this activity recovered in the air pouch washing supernatants. Comparison for each replenishment group was performed for LPS (□) vs. PBS (○) (**$P < 0.05$, ***$P < 0.01$, ****$P < 0.001$).

**FIG. 6.** Effects of cycloheximide (CHX) (1 mg/kg, i.p. 2 h before LPS) with the restoration of LPS-induced neutrophil recruitment and of following replenishment with alveolar macrophages in rat air pouches. Animals were treated with CHX or its vehicle, i.p. for 2 h before bronchoalveolar lavage. Replenishment was performed with $10^6$ macrophages (1 ml) for 0.5 h, then LPS or PBS stimulation were tested (200 ng, 2 h, 1 ml). Results are expressed as mean ± SEM of total number of cells for $n = 6$ experiments for the recruitment and of the TNF-α-like activity (inset) recovered in the air pouch washing supernatants for $n = 6$ under the same conditions. Comparison was performed for CHX (□) vs. its vehicle (○) (**$P < 0.01$, ***$P < 0.001$).

**FIG. 7.** Effects of liposome-encapsulated clodronate on neutrophil recruitment and the TNF-α-like activity triggered by LPS in Brown Norway rat air pouches. Liposome-encapsulated clodronate and empty liposomes were administered under a volume of 0.3 ml into the 7-day-old air pouches, 96 h before LPS. Results are expressed as mean ± SEM of number of neutrophils per field (**$P < 0.01$; ***$P < 0.001$).
Anti-mouse TNFα polyclonal antibodies suppressed the LPS-induced neutrophil recruitment and the generation of TNFα-like activity in rat air pouches

Under conditions where both LPS-induced neutrophil recruitment and TNFα-like activity were significantly inhibited by anti-mouse TNFα polyclonal antibody (0.7 ml into the pouch, 0.5 h before LPS), a treatment with non-immune polyclonal antibodies was ineffective (control: 15611 ± 4236 10^3 neutrophils vs. treated: 3888 ± 411 10^3 neutrophils, P<0.05 (Fig. 8); control: 7.3 ± 1.2 ng/ml of TNFα-like activity vs. treated: 0.11 ± 0.08 ng/ml of TNFα-like activity, P<0.01 (Fig. 8, inset; for n = 4 animals).

Discussion

The injection of LPS into the rat air pouch resulted in a potent time- and dose-dependent recruitment of neutrophils. Suppression of this recruitment by low amounts of the protein synthesis inhibitor cycloheximide and by dexamethasone, injected into the pouch, suggested the involvement of a local target, capable of producing a secondary mediator. Since the concomitant injection of cycloheximide and LPS failed to block neutrophil recruitment, the 2 h interval required for inhibition is probably accounted for by the time needed for inhibition of protein synthesis. Alternatively, cycloheximide may induce apoptosis, an active process requiring protein and RNA synthesis and involving the degradation of nuclear DNA.

Although apoptosis is prevented in most cells

by cycloheximide, HL60 cells, thymocytes and macrophages undergo apoptosis when incubated with micromolar doses of this drug. However, apoptosis is unlikely to account for the suppression of neutrophil recruitment in our experiments, since the conditions used here (2 h, 6 ng ≈ 200 nmol) were previously shown not to induce apoptosis.

Resident mast cells might be affected by cycloheximide and by dexamethasone during LPS-induced neutrophil emigration, as suggested by the results of Matsuda et al. with murine air blebs, a model closely resembling an air pouch but lacking a facsimile synovium. Similarly, Tannenbaum et al. injected compound 48/80 into the rat skin at doses 50 times below ours and provoked a marked neutrophilia within 1–2 h. Compound 48/80 also caused mast cell degranulation, neutrophil adhesion and emigration into the cheek pouch vasculature. Nevertheless, mast cell involvement is unlikely in our model, since the compound 48/80 failed to induce a significant cell infiltration or generation of TNFα-like activity, throughout all time intervals. A more likely hypothesis is that fibroblasts and macrophages of the pouch lining tissue account for the LPS-induced production of chemotactic substances and the consequent neutrophil recruitment, in agreement with the anatomopathological studies of Edwards et al. To verify to what extent this might apply to our model, alveolar macrophages were used to replenish the air pouch and indeed inhibition by cycloheximide of neutrophil emigration and generation of TNFα-like activity was surmounted by transferring fresh alveolar macrophages from control animals, whereas macrophages from cycloheximide-treated animals were not effective, as reported. The use of alveolar macrophages rather than other sources of macrophages is supported by practical considerations concerning macrophage purification and their ability to provide large amounts of TNFα or chemoattractants such as MIP-1α.

Liposomes are particularly efficient in delivering water-soluble drugs into phagocytic cells, since phagocytosis is followed by phospholipase-induced disruption of the liposome phospholipid bilayers and the release of entrapped drugs. In particular, liposome-encapsulated clodronate which should deplete air pouch macrophages37,38 reduced significantly LPS-induced neutrophil recruitment. Since in separate experiments murine peritoneal macrophages were still absent after 5 days treatment (data not shown), the participation of the air pouch macrophage during neutrophil emigration is thus likely. Clodronate is specific for macrophages, since it neither affected the neutrophil population nor other cell types.

Since a potential role for histamine and PAF in LPS-induced neutrophil recruitment into rat air pouches was excluded by selective antagonists, the effectiveness of cycloheximide and dexamethasone strongly suggests the involvement of protein synthesis-dependent mediators such as TNFα. As mentioned, the hypothesized participation of mast cells as a major source of preformed TNFα was ruled out by the failure of compound 48/80 to induce neutrophil recruitment and detectable TNFα-like activity. Among cells that express the TNF gene, the macrophage is unique, insofar as it is capable of secreting-1000 times more TNFα in response to LPS than any other cell type. Furthermore, a TNFα-like activity was detected in the air pouch transplanted with alveolar macrophages from naive, but not from cycloheximide-treated animals. In addition, the rat alveolar macrophage was shown to be an important producer of chemoattractants when stimulated by LPS. Taken together, these results suggest that TNFα-like activity accounts for the LPS-induced neutrophil recruitment in our model. This was supported by the efficacy of an anti-murine polyclonal TNFα antibody to abrogate both LPS-triggered neutrophil recruitment and TNFα-like activity. The resident macrophage is the likely source of this cytokine, as its formation was prevented by both in situ treatments with liposome-encapsulated clodronate and polyclonal antibody. Nevertheless, our results do not clarify whether TNFα acts as a direct chemoattractant to promote neutrophil emigration or if an intermediary chemokine is required, such as CINC/GRO or MIP-1 or 2. Indeed, even though TNFα itself may increase adhesion molecules such as CD11/18 to promote neutrophil emigration, several studies seem to plead for a chemokine networking involving either epithelial cell or endothelial cell.

In summary, we suggest that neutrophil recruitment induced by LPS is a macrophage-dependent event, involving the de novo synthesized TNFα which act directly or via secondary mediators.
