Objective. This study was aimed at investigating whether sevoflurane inhalation induced cognitive impairment in rats with a possible mechanism involved in the event. Methods. Thirty-two rats were randomly divided into four groups of normal saline (NS) + O2, NS + sevoflurane (sevo), amyloid-β peptide (Aβ) + O2, and Aβ + sevo. The rats in the four groups received bilateral intrahippocampus injections of NS or Aβ. The treated hippocampus was harvested after inhaling 30% O2 or 2.5% sevoflurane. Evaluation of cognitive function was performed by Morris water maze (MWZ) and an Aβ1–42 level was determined by ELISA. Protein and mRNA expressions were executed by immunohistochemical (IHC) staining, Western blotting, and qRT-PCR. Results. Compared with the NS-treated group, sevoflurane only caused cognitive impairment and increased the level of Aβ1–42 of the brain in the Aβ-treated group. Sevoflurane inhalation but not O2 significantly increased glial fibrillary acidic protein (GFAP) and ionized calcium-binding adaptor molecule (IBA)1 expression in Aβ-treated hippocampus of rats. Expression levels for Bcl-xL, caspase-9, receptor for advanced glycation end products (RAGE) and brain-derived neurotrophic factor (BDNF) were significantly different in quantification of band intensity between the rats that inhaled O2 and sevoflurane in Aβ-treated groups (all \( P < 0.05 \)). Interleukin- (IL-) 1β, nuclear factor-xB (NF-xB), and inducible nitric oxide synthase (iNOS) mRNA expression increased after the rats inhaled sevoflurane in the Aβ-treated group (both \( P < 0.01 \)). There were no significant differences in the change of GFAP, IBA1, Bcl-xL, caspase-9, RAGE, BDNF, IL-1β, NF-xB, and iNOS in the NS + O2 and NS + sevo group (all \( P > 0.05 \)). Conclusion. Sevoflurane exacerbates cognitive impairment induced by Aβ1–40 in rats through initiating neurotoxicity, neuroinflammation, and neuronal apoptosis in rat hippocampus.

1. Introduction

The hippocampus, a brain area critical for learning and memory, is especially vulnerable to damage at early stages of Alzheimer’s disease (AD) [1]. Some evidence support that amyloid-β (Aβ) peptide is a key trigger of AD pathogenesis [2]. It has been found that the Aβ-associated increases in bone morphogenetic protein 6 (BMP6) expressions were accompanied by reduced markers of neurogenesis in the hippocampus of patients with AD [3]. Aβ is obtained by hydrolysis of its precursor protein APP, and only aggregated Aβ is neurotoxic, leading to synaptic dysfunction and impaired memory. Injection of aggregated Aβ polypeptide fragments into the brain of rats can mimic the development of senile...
plaque in the brain of AD patients, cause damage to the nervous system, and lead to cognitive impairment in experimental animals.

The incidence of AD was approximately 13% in people over 65 years of age, and about 66 million patients over the age of 65 require surgery per year worldwide. In other words, nearly 8.5 million AD patients require anesthesia each year [4]. In recent years, the potential neurotoxicity of inhaled anesthetics has attracted the attention of many researchers. Older people are more likely to have higher CNS complications after anesthesia surgery. Neurotoxicity of inhaled anesthetics is very similar to that of AD-related pathologies. Studies have shown that the use of halogen anesthetics, including sevoflurane, increases the oligomerization/deposition of Aβ and the phosphorylation of tau protein [5]. However, the existing epidemiological studies cannot conclude that the toxicity of anesthetics to the central nervous system is an independent risk factor for AD. A meta-analysis of 15 case-control studies showed no association between anesthetic exposure and AD [6]. In recent years, the impact of inhaled anesthetics on the elderly population has drawn attention [7] and also needed further data to explore.

Sevoflurane is an inhaled volatile anesthetic agent that is widely used in pediatric practice [8]. Studies have shown that the sevoflurane induces neuroinflammation by upregulating the expression of inflammatory cytokines such as tumor necrosis factor-α (TNF-α) and interleukin-1β (IL-1β) and resulted in the increase of Aβ expression, hyperphosphorylation of tau, neuronal apoptosis, and subsequent cognitive impairment [9–11]. The effects of sevoflurane on cognitive ability were reported in aged rats [11, 12]. In the elderly population, there were many AD patients. Therefore, it is necessary to explore the effect of sevoflurane on cognitive function and pathological changes of the brain in AD patients and in this study we used the Aβ-treated rats to imitate the AD patients.

Therefore, the purpose of this study was to investigate whether sevoflurane inhalation impairs cognitive function with a possible mechanism(s) in AD model rats established by Aβ injection. Our findings not only provide information regarding the effects of sevoflurane on the Aβ-injected hippocampus but also suggest that cognitive impairment is due to multiple mechanisms leading to hippocampal dysfunction.

2. Materials and Methods

2.1. Animals. Male Sprague-Dawley (SD) rats weighting 230–280 g were purchased from the Experimental Centre of Animals at China Medical University. The animals at 12 weeks of age were housed in an environmentally controlled animal facility of the center for the duration of the experiments. Thirty-two rats were randomly divided into four groups including normal saline (NS) + O2, NS + sevoflurane (sevo), Aβ + O2, and Aβ + sevo. We took 8 rats from each group to perform the experiment. Another four rats were taken from each of the NS + sevo and Aβ + sevo groups to test the vital signs of sevoflurane inhalation and then sacrificed after the test. All procedures have been reviewed and approved by the Research Review Committee of China Medical University.

2.2. Bilateral Intrahippocampus Injection and Sevoflurane Inhalation. Oligomeric Aβ1–40 solution (Sigma, USA) was prepared for rats receiving bilateral intrahippocampus injections at a concentration of 5 μg/μl. The solution was incubated in an incubator at 37°C for one week and stored at 4°C until use. The sites of injection were selected at the hippocampal CA1 region in the right and left anterior positions (3.0 mm posterior to the bregma, 2.2 mm lateral to the midline, and 3.5 mm beneath the surface of the skull). Two stainless-steel syringes were inserted through a guide cannula to produce 0.5 mm below the tips of the latter. Then, aliquots of 2 μl of NS or Aβ1–40 were gently injected into both sides of the CA1 region within 5 min, according to our protocol. The needles were left in place for an additional 10 min to allow for diffusion of the injected solution. Before the injection of Aβ1–40 or NS, the rats were anesthetized by intraperitoneal injection of 10% chloral hydrate (250 mg/kg).

The rats in each group were exposed to 2.5% sevoflurane or 30% O2 for 4 hours after 14 days of injection of NS or Aβ. The method of sevoflurane inhalation was described as follows: the rats inhaled sevoflurane using a self-made anesthesia chamber (50 cm × 30 cm × 30 cm). The anesthesia chamber was kept at 37°C warm water bath and had two ventilating holes inside: the superior one connected to an anesthesia pump and the inferior one connected to a gaseous monitor. The rats in the NS + sevo group and Aβ + sevo group were anesthetized with 5% sevoflurane in the anesthesia chamber firstly. After 2 minutes, the rats were unconscious, and then the rats were treated by 2.5% sevoflurane and 30% O2 for 4 h (flow rate = 1.5 l/min). Rats in the NS + O2 group and Aβ + O2 group were given only 30% oxygen inhalation for 4 hours in the anesthetic chamber.

2.3. Observation of Vital Signs of Sevo Inhalation. Some of the NS and Aβ-treated rats (n = 4) were lightly anesthetized with sevoflurane by an anesthesia machine (MATRX, US) when inhaling 2.5% sevoflurane for 4 hours. The rats were surgically treated with catheterization inserted into a carotid artery, and the other end was connected to a pressure transducer (ADInstruments, New Zealand). Hemodynamic parameters (mean arterial pressure (MAP), heart beats, pH, PaCO2, PaO2, and HCO3−) of the rats were continuously monitored for 4 hours using a blood gas analyzer (GE, US) when inhaling 2.5% sevoflurane. These rats were used to explore the impacts of sevoflurane on the vital signs of the rat model, and they were sacrificed after the test.

A concentration of sevoflurane was selected for the animals according to the previous studies (13–15). The rest of the rats (32 rats) were followed according to our protocol and started to inhale O2 or sevoflurane for 4 hours using a self-made anesthesia chamber on day 14 after injections of NS or Aβ (Figure 1).

2.4. Morris Water Maze Experiment. To detect the difference in the learning and memory ability of rats in each group before the AD model being established, Morris water maze
Those animals started to inhale 30% O\textsubscript{2} or 2.5% sevo
system (Yishu Info, China). If the rat did not
platform) were recorded by the Any-Maze video-tracking
swimming speed and escape latency (the time from which
form within 90 seconds, they will be guided to the platform
and then all rats were allowed to swim freely until the plat-
water maze was a round pool (diameter: 160 cm, height:
quarters (I, II, III, and IV) according to 4 equidistant points
obtained with centrifugation (2500 r/min \times 15 min) at 4\textdegree C and placed in a clean plastic screw-cap vial for ELISA. The protein concentration of the supernatant was determined by NanoDrop 2000 spectrophotometer (Thermo Scientific, US).

\( \text{A}\beta_{1-42} \) peptide in the hippocampus tissue of the grouped animals was identified using an antibody against the murine \( \text{A}\beta \) (dilution, 1:200) from Santa Cruz (CA, US). The expression level of protein in the supernatant from the tissue was measured using ELISA according to the manufacturer’s directions (Shanghai Xi Mei Chemical Co. Ltd., China). Briefly, 100 \( \mu \)l of the substrate solution was added to 100 \( \mu \)l of the sample in microtiter plates in duplicate tests and then incubated for 30 min at 37\textdegree C. The reaction was stopped by adding 50 \( \mu \)l of 4 M sulfuric acid, and the OD values were read in a microtiter autoreader at 450 nm.

\caption{Schematic representation of study designs. Animal model of Alzheimer disease was established with injection of NS or \( \text{A}\beta \) on day 7. Those animals started to inhale 30% \( \text{O}_2 \) or 2.5% sevo after 14 days of the above injection.}
\end{figure}

2.6. Immunohistochemical Staining. We took 100 mg hippocampus tissue to perform immunohistochemical staining. Some of the tissues were fixed with formaldehyde (10%) for 24 hours and then embedded in paraffin before cutting into 5 \( \mu \)m sections. For IHC staining, hippocampus tissues were infiltrated in PBS containing 4\% (v/v) paraformaldehyde for 30 min and then dehydrated and embedded using paraffin. Sections (5 \( \mu \)m) of the specimens were made, and they were taken care to prevent overstretching. The sections were incubated with rabbit monoclonal anti-glia fibrillary acidic protein (GFAP) (dilution, 1:1000) or ionized calcium-binding adaptor molecule 1 (IBA1) (dilution, 1:500) antibody from Santa Cruz (CA, US) as the primary antibody for at least 18 hours at 4\textdegree C. A horseradish peroxidase-conjugated goat anti-rabbit IgG antibody (dilution, 1:500) was incubated as the secondary antibody for 1 hour at room temperature after the sections were washed with PBS. The sections were photographed using light microscopy (Olympus, Japan) with amplification at 400x.
2.7. Electrophoresis and Quantification of Proteins. Specimens of the hippocampal region were taken from the grouped animals. Aliquots (10 μg/well) of hippocampal lysate were size-fractionated on a 4–20% SDS-PAGE gel and transferred to a nitrocellulose membrane and blocked with 5% nonfat dried milk in TBS. The membrane was individually incubated with anti-GPAP (dilution, 1:500), anti-IBA1 (dilution, 1:500), anti-Bcl-xL (dilution, 1:1000), anti-caspase-9 (dilution, 1:2000), and anti-receptor for advanced glycation end products (RAGE) (dilution, 1:1000) or anti-brain-derived neurotrophic factor (BDNF) (dilution, 1:1000) (Santa Cruz, CA), and β-actin (dilution, 1:500) (BioVision, US) as the primary antibodies at 4°C overnight and then incubated with horseradish peroxidase-conjugated secondary antibody (dilution, 1:2000) after washing with TBS. Proteins were quantified using gel image analysis system and relative band intensity was calculated as % of the intensity of the β-actin protein band.

2.8. Measurement of IL-1β, Nuclear Factor-xB (NF-xB), and Inducible Nitric Oxide Synthase (iNOS) mRNA. Specimens of the hippocampal region were taken from the grouped animals on day 7 following the last exposure and homogenized using a rapidly oscillating masher. IL-1β, NF-xB, and iNOS mRNA expression levels in the region were assessed by using SYBR Premix Ex TaqTM (Takara, Japan). The following forward primers for the IL-1β, NF-xB, iNOS, and β-actin mRNA were used a sequence in 5′-GCTGTGGGAGTCTACCTAGTGTCTTG-3′, 5′-ACTGCCCAGATGGCTTCTAT-3′, 5′-TCCACCTCCTCTCCCTAAGCTT-3′, 5′-CTTAGTTGC-3′ respectively. Revers primers for the IL-1β, NF-xB, iNOS, and β-actin mRNA were 5′-AGTCTGCTATCCACGAGCAG-3′, 5′-CTGGATGCGCTGGCTAA-3′, 5′-CTGGATGCGCTGGCTAA-3′, 5′-CTTAGTTGC-3′. Briefly, total RNA in the specimens was extracted using a tissue homogenizer in Qiagen lysis buffer (Qiagen, UK), and purified of RNA was performed with Qiagen RNeasy minicolumns (Qiagen, UK) following the manufacturer’s protocol. RNA was quantified using the NanoDrop ND-1000 spectrophotometer (Thermo Fisher, USA) and amplified and biotin-labeled with NuGEN’s Ovation System, according to the manufacturer’s instructions (Roche, Switzerland). The yield of the total RNA per replicate varied from 0.6 μg to 2.0 μg. 50 ng of the RNA was added in a SYBR qPCR master mix for real-time RT-PCR. The units from target gene expression in the grouped samples were normalized by the β-actin value. Contents of IL-1β, NF-xB, and iNOS mRNA were expressed as a fold change as compared to the expression level of β-actin mRNA.

2.9. Statistical Analysis. Values were expressed as mean ± standard deviation (SD) on the results. Statistical analysis was performed using Statistical Package for the Social Science (SPSS) version 21.0 (SPSS, IL). Student t-test was used to compare measurements of two groups. A P value of <0.05 was considered statistically significant.

3. Results

3.1. Vital Sign Measurement. To check whether inhalation of sevoflurane was toxic to animals, 4 rats in the NS + sevo group and Aβ + sevo group were monitored with the inhaled gas in the preexperimential study. The data were collected during the length of 1–4 hours of time, and the results are shown in Figure 2. 2.5% sevoflurane inhalation alone did not show significant differences in measurements of MAP (Figure 2(a)), heart beats (Figure 2(b)), pH (Figure 2(c)), PaCO2 (Figure 2(d)), PaO2 (Figure 2(e)), and HCO3 (Figure 2(f)) among 4 different time points (1, 2, 3, and 4 h) for the NS + sevo group (all P > 0.05). The similar results were obtained among 4 different time points (1, 2, 3, and 4 h) in the Aβ + sevo group. These results indicated that 2.5% sevoflurane inhalation for 4 hours had no effect on the vital signs of NS and Aβ-treated rats and no hypoxia or carbon dioxide accumulation. The concentration and the length of time for sevoflurane inhalation were feasible and appropriate in the animals, which did not find toxic effects in vital sign monitoring.

3.2. Effects of Sevoflurane on Cognitive Ability. Spatial probe test and navigation test were performed to determine the effect of sevoflurane on the cognitive ability since the hippocampal formation should be the first brain region to exhibit neurodegeneration in AD, and determination of AD-related alterations in hippocampal function should be central of the AD diagnosis. For the spatial probe test and navigation test, the time spent in exploration of the original platform and the escape latency were recorded respectively on day 7 in four groups (Figures 3(a) and 3(b)). The results showed that there were no differences in the time spent in exploration of the original platform and escape latency between the NS + O2 and NS + sevo group on day 7 (P > 0.05, Figures 3(a) and 3(b)). In contrast to NS-treated groups, there were significant differences in the time spent in exploration of the original platform and escape latency on day 7 between the Aβ + O2 and Aβ + sevo group (P < 0.05, Figures 3(a) and 3(b)). The results indicated that the Aβ-treated rats with sevoflurane inhalation displayed worse performance of cognitive ability. No significant differences in the performances of navigation on the fourth day were recorded as the pretreatment scores in the 4 groups.

3.3. Aβ1-42 Level in Hippocampus. For understanding the effect of sevoflurane on AD, experimental rats received bilateral intrahippocampus injections of NS or Aβ1-40 and then inhaled 30% O2 or 2.5% sevoflurane, respectively. The average values (pg/ml) for the Aβ1-42 protein product in hippocampus tissues harvested on day 7 were shown in Figure 3(c). The Aβ1-42 level in the hippocampus of the Aβ-treated rats with sevoflurane inhalation was obviously higher than that in the O2 exposure group (P < 0.05, Figure 3(c)).

3.4. Expression of GFAP and IBA1 in Hippocampus. Protein expression in rat hippocampus was examined using an IHC method in the presence of 30% O2 and 2.5% sevoflurane. The results are shown in Figure 4. Positive responses of
GFAP and IBA1 proteins to their antibodies were observed in the tissues stained in dark brown color in the images (Figures 4(a) and 4(b)). Astrocytes and microglia with the expression of GFAP and IBA1 proteins are distributed in all CA1 layers of the hippocampus. Then, we performed the Western blotting to determine the expression level of GFAP and IBA1. There were significantly higher expressions of GFAP and IBA1 in the Aβ+ sevo groups compared to the Aβ+O2 groups (P < 0.01, Figures 4(c)–4(e)). No significant differences were found between the NS+O2 and NS+sevo groups on day 7 (P > 0.05). These indicated that sevolurane inhalation obviously increased GFAP and IBA1 protein expression in the Aβ-treated hippocampus of rats at the indicated times.

3.5. Expression of Bcl-xL, Caspase-9, RAGE, and BDNF in Hippocampus. Bcl-xL, caspase-9, RAGE, and BDNF protein expressions in the hippocampus of rats were examined using Western blotting analysis. The results are shown in Figure 5. The intensities of caspase-9 (Figures 5(a) and 5(c)) and RAGE (Figures 5(d) and 5(f)) proteins in the Aβ-injected hippocampus of rats that received sevolurane were significantly higher than those of the rats exposed to O2 on day 7 (all P < 0.05). However, the intensities for Bcl-xL
The level of Aβ in the hippocampus. IL-1β 3.6. IL-1β + O2 group on day 7. Navigation test was performed after inhalation of 30% O2 or 2.5% sevoflurane, and the time spent in exploration of the original platform was recorded (a). The results were expressed as a ratio (%) as compared to the NS + O2 or Aβ + O2 group on day 7, and the escape latency was recorded (b). The results were expressed as seconds as compared to the NS + O2 or Aβ + O2 group at the given times. After the rats inhaled 30% O2 or 2.5% sevoflurane in the presence and absence of Aβ, hippocampus tissues of the treated rats were harvested. And then, the level of Aβ1-42 in the supernatant from the tissue was determined by ELISA (c). *P < 0.05 vs. Aβ + O2 (n = 8).

(FIGURES 5(a) and 5(b)) and BDNF (Figures 5(d) and 5(e)) proteins in the hippocampus of the Aβ-injected rats exposed to sevoflurane were obviously lower than those of the rats with O2 inhalation on day 7=all P < 0.05. No significant differences in the expression of Bcl-xL, caspase-9, RAGE, and BDNF between the NS + O2 and NS + sevo groups on day 7 (all P > 0.05).

3.6. IL-1β, NF-κB, and iNOS mRNA Expression in Hippocampus. IL-1β, NF-κB, and iNOS mRNA expressions in NS- and Aβ-injected hippocampus of rats were determined on day 7. IL-1β, NF-κB, and iNOS mRNA levels were calculated as a fold change in reference with the expression level of β-actin mRNA. The results of IL-1β, NF-κB, and iNOS expression on day 7 were shown in Figure 5. Significant differences were found in the three gene expressions between Aβ + O2 and Aβ + sevo groups (all P < 0.01, Figures 5(g)–5(i)).

4. Discussion

Some hypotheses attribute the delayed neurocognitive deficits produced by sevoflurane to direct neurotoxic effects [6–17]. Potential risks were examined in rats that received 30% O2 or 2.5% sevoflurane for 4 hours after the hippocampus of rats was bilaterally injected with NS or Aβ, and the 2.5% sevoflurane only has neurotoxic effects to rats injected with Aβ in the hippocampus. Our results revealed that vital signs including measurements of MAP, heart beats, pH, PaCO2, PaO2, and HCO3− were not obviously changed at 4 different time points (1, 2, 3, and 4 h) for the NS + sevo group or Aβ + sevo group, suggesting that intervention of sevoflurane was not toxic to these rats at duration and concentration of the inhaled anesthetic in the animal study. These clinical observations not only displayed the quality initiative in the clinical practice of anesthesiology but also set up fundamental steps in the experimental design for further studies.

Inhalation anesthesia with sevoflurane but not O2 in Aβ-treated rats resulted in obvious increases in the length of time for escape latency, indicating that sevoflurane inhalation was able to induce neurocognitive dysfunction in the rats as assessed by the MWM. This result was consistent with other research on the escape latency from the hidden platform [18]. Anesthetic drugs may cause widespread neurodegeneration in the developing brain and persistent learning deficits linked to anesthesia-induced neurotoxicity [19, 20]. Although inhalation anesthesia with sevoflurane produces neural toxicity in animals, the precise mechanism of behavioral abnormalities remains elusive [21, 22].

Deposited Aβ protein represents an important neuro-pathological hallmark of AD pathogenesis [23]. Several studies have shown that sevoflurane exposure of animals significantly increases neuronal apoptosis in several brain regions [21, 24]. Our data displayed that the Aβ1-42 level in rat hippocampus significantly increased on day 7 after inhaling sevoflurane, suggesting that inhalation of the anesthetic agent induced neuron loss based on the reports in which the AD-associated Aβ peptide has been shown to induce apoptotic neuronal death [25, 26]. Both the Aβ1-40 and Aβ1-42 Peptides are ubiquitous in biological fluids [27], but Aβ1-42 is generally considered to be more pathogenic in AD patients [28, 29]. Given our data, it is reasonable to consider that sevoflurane inhalation caused cognitive decline partly due to intracellular Aβ1-42 accumulation that in turn disrupted hippocampal function.

It has been known that GFAP and IBA1 are used as markers of astrocytic and microglial activation [30]. In immunohistochemical studies, GFAP and IBA1 protein expressions in the Aβ-treated hippocampus of rats obviously increased on day 7 after inhaling sevoflurane but not O2, suggesting that such exposure mainly acted on these glial cells and aggravated neuroglial activation in the hippocampus. GFAP is an intermediate filament protein, and its immunostaining is largely used to colocalize astrocytes with...
Aβ plaques [31]. IBA1 as a calcium-binding protein plays an important role in showing microglial activation that is closely associated with nearly all compact deposits of the Aβ-protein found in the senile plaques of AD [32]. Since astrocytes and microglia with the expression of GFAP and IBA1 proteins are distributed in all CA1 layers of the hippocampus [33], it is likely that impaired interplay among these neural cells is responsible for derangements from inhalation anesthesia with sevoflurane to abnormal cognitive processes.

In Western blotting analysis, Bcl-xL, caspase-9, RAGE, and BDNF protein expressions in the Aβ-treated hippocampus tissues were different from the rats exposed to O2 and sevoflurane. Caspase-9 and RAGE protein expressions in the Aβ-treated tissues significantly increased, whereas Bcl-xL and BDNF expressions decreased in the rats exposed to sevoflurane as compared to those with O2 exposure. These findings led us to conclude that inhalation anesthesia with sevoflurane initiated diverse effects of neural cells in the hippocampus of rats. The pathology of AD is characterized by an accumulation of misfolded proteins and inflammatory changes, which results in region-specific loss of synaptic contacts and neuronal cell death [34]. It has been known that defective control of apoptosis appears to play a central role in the pathogenesis of neurodegenerative diseases [35]. Bcl-xL protects against caspase-9-dependent apoptosis in the nervous system [36]. Targeted disruption of Bcl-xL causes massive death of immature neurons whereas disruption of caspase-9 leads to decreased neuronal apoptosis and neurodevelopmental abnormalities [37]. Since activation of apoptotic death pathways is related to the Bcl-xL-caspase-9 interaction [37], it is reasonable to speculate that sevoflurane exposure induced cognitive deficits and decline probably through potentially disrupting the balance between the Bcl-xL and caspase-9 expression levels in apoptotic cell death regulation.

---

**Figure 4:** Sevoflurane inhalation increased protein expression of GFAP and IBA-1 in the hippocampus determined by immunochemistry and Western blot. Immunochemistry was used to determine the GFAP (a) and IBA1 (b) expression levels in the NS- or Aβ-treated hippocampus of rats after inhaling 30% O2 and 2.5% sevoflurane at the indicated times. Western blot was also used to determine the expression of GFAP and IBA1 in the four groups (c). The results in (d) and (e) were calculated as % of the intensity of the β-actin protein band and expressed as a fold change in reference to their controls. **P < 0.01 vs. Aβ + O2 (n = 8).**
Inhalation anesthesia with sevoflurane increased RAGE expression and decreased Aβ level in the Aβ-treated hippocampus, suggesting that the changes in these two protein expressions were partly related to cognitive impairment. RAGE, the receptor of advanced glycation end products, is thought to be one of the potential contributors to the neurodegeneration and neuroinflammation [38, 39]. An increased expression of RAGE is observed in regions of the brain affected by AD [40]. BDNF is one of the neurotrophic factors that play key roles in modulating synaptic transmission, neuronal survival, and axonal guidance, as well as memory formation and cognition [41, 42]. According to experimental data, BDNF protects neurons against Aβ-induced neurotoxicity and contributes to increased Aβ degradation [43]. Since RAGE and BDNF expressions were significantly changed in the animal model, it is very likely that sevoflurane inhalation...
caused cognitive decline in the processes of learning and memory through triggering neuroinflammation and neurotoxicity in the hippocampus tissue.

Inhalation anesthesia with sevoflurane resulted in increased IL-1β, NF-κB, and iNOS mRNA expression in the Aβ-injected hippocampus of rats on day 7, indicating the neuronal inflammatory reactions involved in the hippocampus tissue. IL-1β has been considered to be a major proinflammatory cytokine in the onset of inflammatory process and plays a key role in neuronal damage and losses observed in AD [44]. NF-κB has long been considered a prototypical proinflammatory signaling pathway, largely based on the activation by proinflammatory cytokines such as IL-1β [45]. In AD patients, iNOS mRNA was increased, suggesting high-output NO production [46], which was consistent with our results. Since blocking or neutralizing IL-1β in an AD mouse model largely protects from cognitive deficits [47], it led us to consider that the increased IL-1β level would drive potent neuroinflammatory changes contributing to neuronal death in the brain.

Studies have shown that sevoflurane has no damage to normal rats, and in our study similar results were obtained in the rats with injection of NS into the hippocampus. Studies have shown that sevoflurane can exert damage for the aged or neonatal rats, and the results were similar to ours in the Aβ-treated rats, further demonstrating that sevoflurane has an effect on the fragile brain, in which sevoflurane can affect the vulnerable brains.

In conclusion, this study indicates that inhalation anesthesia with sevoflurane causes cognitive deficits and decline through the underlying mechanisms by which neurotoxicity, neuroinflammation, and neuronal apoptosis are developed in the Aβ-injected rat hippocampus.
