We discuss dynamic system performance evaluation in the river port utilizing queuing models with batch arrivals. The general models of the system are developed. This system is modelled by $M^X/M/n/m$ queue with finite waiting areas and identical and independent cargo-handling capacities. The models are considered with whole and part batch acceptance (or whole and part batch rejections) and the interarrival and service times are exponentially distributed. Results related to the batch blocking probability and the blocking probability of an arbitrary vessel in nonstationary and stationary states have been obtained. Numerical results and computational experiments are reported to evaluate the efficiency of the models for the real system.

1. Introduction

Batch arrival queues with a finite waiting areas or finite-buffer space have wide range of applications in computer networks, telecommunications, transportation, manufacturing, banks, management and logistics systems, and so forth. Many results in queuing theory have been obtained by considering models, where customers arrive one by one and are served individually. However, in numerous real-world situations such as previous; mentioned various practical areas, it is frequently observed that the customers arrive in groups. Consequently, their operation processes can be adequately modelled by batch arrival queue.

Models of this type have also applications in modelling the port systems, showing that initial Markovian models are very accurate in determining a port performance. At seaport
2 Mathematical Problems in Engineering

and river port terminals such as bulk material port handling systems, the situations where vessels arrive in groups are naturally common.

In a port queuing system that does not serve each vessel immediately upon arrival, a vessel will attempt to arrive at a time that will minimize the expected queue length. The consequences of such behavior are analyzed for a queue with finite waiting areas. The characteristics of such a system are then compared for two possible vessel batch acceptance models: whole batch acceptance and part batch acceptance. Closed-form expressions for the state probabilities for whole batch acceptance model described by the nonstationary multiserver queuing system related to the uniform random variable $X$ with the distribution given by $a_k = P(X = k)$, $k \geq 1$, ($k$ is a number of vessels in group), where $a_1 = a_2 = \cdots = a_{m+n} = a$, are obtained in [1]. This paper extends earlier work on the nonstationary queue length distribution of a batch arrival into the system with finite waiting area by considering multiserver queuing systems [1]. This is a Markovian type of finite batch queue and whole batch acceptance. The whole batch acceptance model when $X$ has the geometric probability distribution function and part batch acceptance model (with the uniform and geometric random variable $X$) does not seem to be possible to obtain closed-form expressions for the state probabilities or even the generating function of these probabilities.

Consequently, this paper considers a finite waiting areas batch arrival queue with identical and independent cargo-handling capacities: $M^X/M/n/m$, where $m$ denotes the number of waiting areas. The main aim of this paper is to discuss the analytic and computational aspects of these models with whole and part batch acceptance. After putting our study into context, in Section 2, we give the background in modelling and port terminal operations. Section 3 presents models formulation and analytical models applied to blocking probability calculations with batch arrivals and finite waiting areas. Examples of numerical results are presented in Section 4 with different results for analysis of the real system. Finally, Section 5 concludes the paper.

2. Background in Modelling and Port Terminal Operations

This paper analyses the $M^X/M/n/m$ queue, where vessels arrive in batches of random size. Unlike the other batch arrival queue with finite waiting areas (anchorage), batches which upon arrival find not enough area at the anchorage are either fully or partially rejected. Some queuing protocols are based on the whole and part batch acceptance models, and it is also known as the total or part batch rejection policy. The stochastic characteristics of the port operation are as follows: time of arrival of single vessel or in batch (barge tows) in the port cannot be precisely given; the service time is a random variable depending on handling capacities of berths, carriage of barges, the size of an arriving group, and so forth, and the berths are not always occupied (in some periods there are no barges—the capacities are underutilized, and there are the time intervals of high utilization when the queues are formed).

The port operation and vessel movement include the following: waiting in the anchorage areas (if all anchorages are occupied, the vessels or the barge tows are rejected, or if the vessels or the barge tows are larger in size than the number of available free waiting areas fills the free positions and the remaining vessels of the group are rejected and have to go to another waiting area), vessels move from anchorage to berth, loading or unloading at the berth, and towing of barges after the loading/unloading to the anchorage area or leaving the port. This cycle is called the turnaround time for the vessels in the port.
The ports or, more precisely, the anchorage-ship-berth (ASB) links are considered as queuing models with batch arrivals, single service, and limited queues at an anchorage. In the port, the ASB link is assumed as follows: the applied queueing system is nonstationary and stationary, with finite waiting area at anchorage; the sources of arriving pattern are not integral parts of ASB link; the service channels are berths with similar or identical and independent cargo-handling capacities; the units arrivals can be single vessels and groups as barge tows; all barge tows and single vessels at anchorage are waiting to be serviced; the service time is a continuous random variable; the size of an arriving group is a random variable; the queue length or the number of waiting anchorage areas are finite and given; interarrival times, the batch sizes, and service times are mutually independent.

The past 30 years show rising interest in the research of port and terminals systems modelling as well as their subsystems involving port equipment. Earlier research related to a bulk port, particularly to the ASB link modelling, using simulation and queuing theory, is summarized in [2–5]. Problems in modelling and simulation in the field of port equipment are shown for instance in [6, 7].

There are numerous articles dealing with infinite and finite batch arrivals and service queues. For example, in [8] the sojourn time distribution, loss probability of an arbitrary flow, and arbitrary admitted flow in a multiserver loss queue with a flow arrival of customers is analyzed. In the case of the case of the waiting line as a whole, which has a limited capacity, specified by a fixed maximum number of customers or finite-buffer space, queues have been analysed by several researchers in the past. Apart from the classical references [9–12] used for describing the models here, it was necessary to review the following articles. In [13], the ergodic queue length distribution of a batch service system with finite waiting space by the method of the embedded Markov chain is discussed. The analysis of the $M^X/G^Y/1/N$ queue is given in [14]. In [15], the $M^X/G^Y/1/K$ queue by Cohen’s methods is investigated. The $M^X/M/m/s$ queue has been analyzed in [16], where several results related to blocking probabilities, the distribution of the number of customers in the system, the cumulative distribution function of the waiting time in the queue, and some numerical results for the single-server system are presented. In [17], two different methods to study the behavior of a finite queue with batch Poisson inputs, and synchronous server in a computer network are proposed. The analysis $M(n)/G(n)/1/K$ queue is given in [18], while in [19], the $M/G/1/K$ queue with push-out scheme is analyzed. In [20], the performance analysis of a discrete-time finite-buffer queue with batch input, general interarrival, and geometric service times ($GI^X/Geom/1/N$) is presented. In [21], the $GI^X/M/c/N$ queue through a combination of the supplementary variable and the embedded Markov chain techniques is proposed and analyzed. The $M^X/G^Y/1/B + B$ queue with a finite-buffer batch-arrival and batch service queue with variable server capacity has been considered and analysed in [22]. In [23], a performance analysis of finite-buffer batch-arrival and batch-service $Geom^X/G^Y/1/K + B$ queue is presented. The analysis $GI^X/MSP/1/N$ queue is given in [24]. In [25], the $GI/BMSP/1/N$ queue with a finite-buffer single-server queue with renewal input, where the service is provided in batches of random size according to batch Markovian service process is analyzed. The batch arrival batch service $M^X/G^Y/1/N$ queue with finite buffer under server’s vacation is analysed in [26]. In [27], the blocking probability in a finite-buffer queue whose arrival process is given by the batch Markovian arrival process was investigated.

One can conclude that the ASB link, as a main port link, has been adequately analyzed and modelled by using different modelling approaches. Various operations research models
and methods in the field of optimizing ASB link modelling are applied more and more in world terminals. In this paper, two models are described by the nonstationary and stationary, multiserver queuing system with finite waiting areas and batch arrival vessels or barge tows into the port system.

3. Mathematical Models Development

We consider a finite waiting areas batch arrival multiserver queue with identical and independent cargo-handling capacities: \( M^X/M/n/m \), where \( m \) denotes the number of waiting areas. The vessels or the barge tows arrive at the terminal according to a time-homogeneous Poisson process with mean arrival rate \( \lambda \). The port terminal has the \( n \) berths for the service. The \( n \) berths have independent, exponentially distributed service times with common average service time \( 1/\mu \) (the mean cargo-handling rate per berth is \( \mu \)). The queue discipline is first come first served by tows batch and random within the tow batch. Apart from the possible arrival of \( n \) vessels for service, there are \( m \) spaces in the waiting queue. The number of vessels \( X \) that arrive for service at the same time is a random variable with distribution given by \( a_k = P(X = k), k \geq 1 \) (whereas \( k \) = number of vessels in group) and mean \( E(X) = \bar{a} \). The interarrival times, the batch sizes, and service times are mutually independent. The maximum number of vessels allowed in the system at any time is \( n + m \).

The service times of service batches (vessels) are independent of the arrival process and the number served. The traffic intensity of the system is \( \theta = \lambda \bar{a} / n\mu \).

For convenience, three different forms for the distribution of \( X \) are considered: uniform distribution with \( a_k = 1/(n + m), 1 \leq k \leq n + m \), geometric distribution with \( a_k = (1 - a)a^{k-1}, k = 1,2,\ldots, \) and \( 0 < a < 1 \), and shifted Poisson distribution with \( a_k = (a^{k-1}/(k-1)!))e^{-a}, k = 1,2,\ldots, \) and \( a > 0 \). Since the waiting area (anchorage) is finite, the following two batch acceptance models are defined.

(I) If the group of vessels arriving into the system finds \( s \) vessels there, then in the case that \( k \leq (n + m) - s \), the whole group will be accepted into the system. Otherwise, that is, if \( k > (n + m) - s \), the group is totally rejected. This is called the whole batch acceptance model related to Figure 1.
(II) In the case when group of \( k \) vessels arriving into the system finds \( s \) vessels there, then \( k \leq (n + m) - s \), the whole group will be accepted. If \( k > (n + m) - s \), the system accepts any \( (n + m) - s \) vessels from the group, while the rest of \( k - ((n + m) - s) \) vessels will be rejected. This is the part batch acceptance model related to Figure 2.

The state probabilities of the systems for Model (I) should be determined by the number of vessels within the system, shown in graph in Figure 1, and then, the following system of differential equations for whole batch acceptance model at the moment \( t \) are given by

\[
\begin{align*}
p'_0(t) &= \left(-\lambda \sum_{i=1}^{n+m} a_i \right) p_0(t) + \mu p_1(t), \\
& \vdots \\
p'_r(t) &= \left(-\lambda \sum_{i=1}^{n+m-r} a_i + r \mu \right) p_r(t) + \lambda \sum_{k=0}^{r-1} a_{r-k} p_k(t) + (r+1) \mu p_{r+1}(t), \quad \text{for } 1 \leq r \leq n-1, \\
& \vdots \\
p'_{n+r}(t) &= \left(-\lambda \sum_{i=1}^{m} a_i + n \mu \right) p_{n+r}(t) + \lambda \sum_{k=0}^{n+r-1} a_{n+r-k} p_k(t) + n \mu p_{n+r+1}(t), \quad \text{for } 1 \leq r < m, \\
& \vdots \\
p'_{n+m}(t) &= -n \mu p_{n+m}(t) + \lambda \sum_{k=0}^{n+m-1} a_{n+m-k} p_k(t). \\&
\end{align*}
\]

\[ (3.1) \]
Analogously, the state probabilities of the systems for Model (II) should be determined by the number of vessels within the system, shown in graph in Figure 2, and hence, the system of differential equations for part batch acceptance model at $t$ is as follows:

$$p_0'(t) = -\lambda p_0(t) + \mu p_1(t),$$

$$\vdots$$

$$p_r'(t) = -(\lambda + r\mu)p_r(t) + \lambda \sum_{k=0}^{r-1} a_{r-k}p_k(t) + (r + 1)\mu p_{r+1}(t), \quad \text{for} \ 1 \leq r \leq n - 1,$$

$$\vdots$$

$$p_{n+r}'(t) = -(\lambda + n\mu)p_{n+r}(t) + \lambda \sum_{k=0}^{n+r-1} a_{n+r-k}p_k(t) + n\mu p_{n+r+1}(t), \quad \text{for} \ 1 \leq r < m,$$

$$\vdots$$

$$p_{n+m}'(t) = -n\mu p_{n+m}(t) + \lambda \sum_{k=0}^{n+m-1} \left(1 - \sum_{i=1}^{n+m-k-1} a_i\right)p_k(t).$$

(3.2)

One of the complexities in the analysis of the models is nonstationary state of work of the systems. The analysis becomes further complicated in the case of multiserver queues as a port systems. The queuing systems for the models are Markovian, and the state probabilities are described by a set of differential equations in the steady state. The first requirement is to determine the state probabilities $p_k(t), \ k = 0, 1, \ldots, n + m.$

Consider the system (3.1) of $n + m + 1$ first-order linear differential equations related to the “uniform” random variable $X$, that is, when $a_1 = a_2 = \cdots = a_{n+m} = a$ (the values $a_i$, with $i > m + n$, must be different of $a$ and 0). By using the normalized condition $\sum_{k=0}^{n+m} p_k(t) = 1$, the last equation of (3.1) becomes

$$p_{n+m}'(t) = -n\mu p_{n+m}(t) + \lambda a \left(1 - p_{n+m}(t)\right).$$

(3.3)

The solution of this differential equation is

$$p_{n+m}(t) = C_0^{(n+m)} + C_1^{(n+m)} e^{-(n\mu + \lambda a)t},$$

(3.4)

where $C_0^{(n+m)} = \lambda a / (n\mu + \lambda a)$ and $C_1^{(n+m)}$ are real constants.
Further by induction based on the recursive method, it can be proved [1] that the solution of system (3.1) is given in the form

\[
p_{n+m-s}(t) = C_0^{(n+m-s)} + \sum_{j=1}^{n+s+1} \sum_{j=1}^{n+j+1} \left( C_j^{(n+m-s)} e^{-\lambda j t} \right), \quad \forall s, \quad 0 \leq s \leq m,
\]

\[
p_{n-1}(t) = C_0^{(n-1)} + \sum_{j=1}^{n+1} C_{m+1+j}^{(n-1)} e^{-(\lambda a_{m+j+1}+(n-j)j)t},
\]

\[
+ \sum_{k=1}^{m+1} C_k^{(n-1)} e^{-(\lambda k+n)t}, \quad \forall l, \quad 1 \leq l \leq n - 1,
\]

\[
p_0(t) = C_0^{(0)} + \sum_{j=1}^{n} C_{m+1+j}^{(0)} e^{-(\lambda a_{m+j+1}+(n-j)j)t} + \sum_{k=1}^{m+1} C_k^{(0)} e^{-(\lambda k+n)t},
\]

where \( C_k^{(l)} \) are suitable real constants.

By substituting the expressions for \( p_i(t) \), \( 0 \leq i \leq m + n \), given by (3.5) in system (3.1) with \( a_1 = a_2 = \cdots = a_{m+n} = a \), and using the initial conditions \( p_0(0) = 1 \), \( p_l(0) = 0 \) for \( i = 1, 2, \ldots, m + n \), we can obtain the recurrence relations between the coefficients \( C_k^{(s)} \). These recurrence relations give the values of each coefficient \( C_k^{(s)} \). Obviously, \( p_{n-l} = C_0^{(n-l)} \) for all \( l \), \( 0 \leq l \leq n \), and \( p_{n+m-s} = C_0^{(n+m-s)} \) for all \( s \), \( 0 \leq s \leq m \) are in fact solutions of the system of linear equations which is stationary analogue to the system (3.1) (see in detail [1]). Observe that any functions \( p_i(t) \), \( 0 \leq i \leq m + n \) can be written as a linear combination of finite number of exponential functions of the form \( e^{-\lambda t} \), with \( C > 0 \).

Unfortunately, the system (3.2) related to the uniform random variable \( X \) (i.e., \( a_1 = a_2 = \cdots = a_{m+n} = a \) cannot be solved using recursive method. Further, if the random variable \( X \) has the geometric probability distribution function, with \( a_k = (1-a)a^{k-1} \), where \( k = 1, 2, \ldots, \) and \( 0 < a < 1 \), or shifted Poisson distribution with \( a_k = (a^{k-1}/(k-1)) e^{-a} \), \( k = 1, 2, \ldots, \) and \( a > 0 \), the systems (3.1) and (3.2) also cannot be solved using recursive method as done in the previous case related to the mentioned random variable \( X \). Hence, MATLAB program is used for solving the corresponding systems (3.1) and (3.2).

### 3.1. Blocking Probability for Both Models

In order to calculate the blocking probability at the moment \( t \) for any considered models in transient (nonstationary) regime, it is necessary to determine the solutions \( p_k(t), k = 0, 1, \ldots, n + m, \) of the corresponding system of differential equations (3.1) or (3.2). As previously noticed, it is outlined that closed-form expressions for time-dependent state probabilities for whole batch acceptance model of multiserver queuing system related to the uniform random variable \( X \) are obtained in [1]. However, the considered systems (3.1) and (3.2) cannot be solved in the closed-form expressions with respect to other batch size distributions (geometric and shifted Poisson distribution for both models and the uniform distribution for Model (II)).

The batch blocking probability at the moment \( t \) is the same for both models, and it is given by the following.

**Proposition 3.1.** The batch blocking probability at the moment \( t \) for models (I) and (II) is

\[
P_b(t) = \sum_{k=0}^{n+m} p_k(t) \sum_{i=n+m-k+1}^{\infty} a_i,
\]

(3.6)
Proof. Given the batch finds exactly \( k, 0 \leq k \leq n + m \), vessels in the system the batch will be blocked at arbitrary moment \( t \) if this batch is bigger than \( n + m - k \) in size. Since \( P(X \geq n + m - k) = \sum_{i=n+m-k+1}^{\infty} P_i(t) \), then by the total probability formula, we immediately obtain (3.6).

Similarly, it can be shown (see [16, 20] related to stationary blocking probability) the following result.

Proposition 3.2. The blocking probability of an arbitrary vessel at the moment \( t \) is given

(a) for Model (I):

\[
P_V^{(1)}(t) = \frac{1}{a} \sum_{k=0}^{n+m} p_k(t) \sum_{i=n+m-k+1}^{\infty} i a_i,
\]

(b) for Model (II):

\[
P_V^{(2)} = \frac{1}{a} \sum_{k=0}^{n+m} p_k(t) \sum_{i=n+m-k+1}^{\infty} (i + k - n - m) a_i,
\]

where \( a \) is the mean batch size.

In the stationary state of work of the system (as \( t \to \infty \)), using the systems of differential equations (3.1) and (3.2), the corresponding set of Chapman-Kolmogorov equations can be easily obtained. Note that as \( t \to \infty \), the stationary blocking probabilities for Models (I) and (II) are \( p_k = \lim_{t \to \infty} p_k(t), k = 0, 1, \ldots \), where \( p_k, k = 0, 1, \ldots, n + m \) are solutions of the system (3.1) or (3.2) in the stationary state of work of the system, respectively. Hence, substituting this into (3.6), (3.7), and (3.8), one obtains the corresponding formulae for stationary blocking probabilities as follows:

\[
\begin{align*}
P_B &= \sum_{k=0}^{n+m} p_k \sum_{i=n+m-k+1}^{\infty} a_i, \\
P_V^{(1)} &= \frac{1}{a} \sum_{k=0}^{n+m} p_k \sum_{i=n+m-k+1}^{\infty} i a_i, \\
P_V^{(2)} &= \frac{1}{a} \sum_{k=0}^{n+m} p_k \sum_{i=n+m-k+1}^{\infty} (i + k - n - m) a_i.
\end{align*}
\]

For example, in the case of uniform distribution \( X \) with \( a_1 = a_2 = \cdots = a_{m+n} = 1/(n+m) \) and hence \( a_i = 0 \) for each \( i > n + m \), the first formula of (3.9) becomes \( P_B = 1/(n+m) \sum_{k=0}^{n+m} k p_k = N_{\text{wss}}/(n+m) \), where \( N_{\text{wss}} \) is the average number of vessels in port.

On the other hand, in the case of geometric distribution \( X \) with \( a_k = (1-a) a^{k-1} \), \( k = 1, 2, \ldots, \) and \( 0 < a < 1 \), after routine calculation the first formula of (3.9) yields \( P_B = \sum_{k=0}^{n+m} a^{n+m-k} p_k \).

For example, in the case of uniform distribution \( X \) with \( a_1 = a_2 = \cdots = a_{m+n} = 1/(n+m) \), and hence, \( a_i = 0 \) for each \( i > n + m \), the second and third formula of (3.9) become \( P_V^{(1)} = 1/((n+m)(n+m+1)) \sum_{k=0}^{n+m} k (2n+2m-k+1) p_k \) and \( P_V^{(2)} = 1/((n+m)(n+m+1)) \sum_{k=0}^{n+m} k (k+1) p_k \), respectively.
4. Port Performance Measures

Performance measures are the means to analyse the efficiency of the port queuing system under consideration. When state probabilities are known, performance measures can be easily obtained. In this section, some performance measures are explained, such as the probability that all the berths are occupied—\( P_{bb} = \sum_{k=0}^{\infty} p_{n+k} \), average number of occupied berths—\( n_{oc} = \sum_{k=1}^{\infty} k \cdot p_{k} \), probability that berth is busy—\( P_{bus} = 1 - p_0 \), probability of existing vessels in queue (vessels at anchor)—\( p_{eq} = \sum_{k=1}^{\infty} p_{n+k} \), average number of vessels at anchor—\( N_w = \sum_{k=1}^{\infty} k \cdot p_{n+k} \), average time that vessels spends at anchor—\( t_w = N_w/\lambda^* \), where \( \lambda^* \) is the effective arrival rate of vessel [9], given by \( \lambda^* = \lambda \sum_{k=0}^{\infty} p_k \sum_{i=0}^{\infty} \frac{a_i}{i^2} \) for Model (I) and \( \lambda^* = \lambda \sum_{k=0}^{\infty} p_k (\sum_{i=1}^{\infty} \frac{a_i}{i^2}) \) for Model (II).

Recall that the all previous formulae except those on \( t_w \) and \( \lambda^* \) are valid in the same forms for nonstationary state (with \( p_k(t) \) instead of \( p_k \)).

4.1. Numerical Results and Discussion

The efficiency of operations and processes on anchorageship-berth (ASB) link has been analyzed through the basic operating parameters such as batch blocking probability, blocking probability of an arbitrary vessel, expected number of occupied berths, probability that all the berths are occupied, probability of existence of vessels in queue (vessels at anchor), expected number of vessels at anchor, and expected time at anchor. The basic characteristics of the system with the batch arrival of units and the limited waiting queue are shown in previous sections. To demonstrate the applicability of the models presented in this paper, a variety of numerical results have been showed for a combination of various parameters and various performance measures are given for the multiple server port system. All the calculations on probabilities and means were done by MATLAB program, but the results are presented after rounding up after the fourth decimal point.

Recall that both systems (3.1) and (3.2) are first order systems of \( m + n + 1 \) linear homogeneous differential equations with constant coefficients, and so, they may be expressed in matrix notation as \( dY/dt = AY \), where \( Y(t) = \{p_0(t), p_1(t), \ldots, p_{n+m}(t)\} \) is a vector-valued function and \( A \) is a square matrix (with constant coefficients). Moreover, if \( \lambda_1 \) is an eigenvalue for \( A \) (i.e., \( \det(A - \lambda I) = 0 \)) with associated eigenvector \( V_1 \) (i.e., \( AV_1 = \lambda V_1 \)), then \( Y(t) = e^{\lambda t} V_1 \) is a solution of the considered system. We used MATLAB to compute the eigenvalues and eigenvectors of a given matrix \( A \) and therefore to calculate the solutions of the corresponding systems.

The first step is to enter the given matrix \( A \): this is done by enclosing in square brackets the rows of \( A \), separated by semicolons. For determining eigenvalues and eigenvectors of \( A \), we enter \([V,D] = \text{eig}(A)\) in order to get two matrices: the matrix \( V \) has (unit length) eigenvectors of \( A \) as column vectors, and \( D \) is a diagonal matrix with the eigenvalues of \( A \) on the diagonal.

On the other hand, in the case of geometric distribution \( X \) with \( a_k = (1 - a)a^{k-1} \), \( k = 1, 2, \ldots \), and \( 0 < a < 1 \), after routine calculations the second and third formula of (3.9) imply \( p_V^{(1)} = \sum_{k=0}^{n+m} (n+m-k+1-a(n+m-k)) p_k a^{n+m-k} \) and \( p_V^{(2)} = \sum_{k=0}^{n+m} a^{n+m-k} p_k \), respectively.

It is interesting to note that \( P_b = P_V^{(2)} \) for the Model (II).
In our computations it is used MATLAB’s numerical procedure “ode45” which is a souped up Runge-Kutta method and it is applied using the syntax

\[ [t, y] = \text{ode45}("diffeqn", [t0, tf], y0), \]

where \( t_0 \) is the initial time, \( tf \) is the final time and \( y0 \) is the initial condition \( y(t0 = y0) \).

In Figures 3(a) and 3(b), the parameters on the ASB link of multiple server systems (\( P_B, P_{V_{1}}^{(1)} \) and \( P_{V_{2}}^{(2)} \)) are presented, as a function of time \((t = 0–50 \text{h})\), and values \( \lambda = 0.2 \) and \( \mu = 0.65 \) for the \( M^X/M/2/12 \) queue with \( \bar{a} = 6 \) and \( \bar{a} = 4 \), and different forms for the distribution of \( X \) (uniform distribution—\( a_k = 1/(n + m) \), where \( 1 \leq k \leq n + m \), geometric distribution—\( a_k = (1 - a)a^{k-1} \), where \( k = 1, 2, \ldots, \) and \( 0 < a < 1 \), and shifted Poisson distribution—\( a_k = (a^{k-1}/(k-1))e^{-a}, \) where \( k = 1, 2, \ldots, \) and \( a > 0 \)). Dimensioning curves are given in Figures 3(a) and 3(b) and show the impact of the nonstationary work order on operating parameters’ changes for batch acceptance strategy in relation to Models (I) and (II). It can be seen that while acceptance strategy makes some appreciable differences for different values of \( \bar{a} \), their effect diminishes with decreasing \( \bar{a} \). Model (I) (accept only whole batches) has always lower batch blocking probability (Figure 3(a)) and has always higher blocking probability of an arbitrary vessel (Figure 3(b)) and hence lower vessel throughput.

Figures 4(a)–4(d) show performance curves for the \( M^X/M/2/12 \) queue. These curves give the effect of batch distribution on the batch blocking probability \( (P_B) \) and blocking probability of an arbitrary vessel \( (P_{V_{1}}^{(1)} \) and \( P_{V_{2}}^{(2)} \)), average number of vessels \( (N_w) \), and average time at anchor \( (t_w) \) as a function of traffic intensity, \( \theta = \lambda \bar{a}/n \mu \). Further, the sensitivity to the batch parameters is noted. Figures 4(a) and 4(b) have a revealing comparison between the \( P_B, P_{V_{1}}^{(1)} \) and \( P_{V_{2}}^{(2)} \) for each model. The relation of the Model (II) curves to the Model (I) curves may be understood by noting that at low traffic equal numbers of batches tend to be affected by blocking, whereas at high traffic, it is the case for equal numbers of vessels.
Figures 4(c) and 4(d) show $N_w$ and $t_w$ as a function of $\theta$ for the $M^X/M/2/12$ queue with $\bar{a} = 4$.

In addition, Table 1 gives the numerical results of parameters on the ASB link of multiple-server systems ($P_B$, $P_V^{(1)}$, and $P_V^{(2)}$, $N_w$ and $t_w$) depending on $\theta$ (0-1) for the $M^X/M/2/8$ queue with $\bar{a} = 4$. All of the calculations have been done in MATLAB program. 

Figures 5(a) and 5(b) express $P_B$, $P_V^{(1)}$, and $P_V^{(2)}$ as a function of anchorage size (number of waiting areas) for both models. These figures include a family of curves for different forms of the distribution of $X$. The constant parameters for these curves are ($\theta = 0.61$ and $\bar{a} = 4$) for

4.2. Experimental Study

This subsection discusses how the developed models can be applied to solve some related problems in river port. In particular, we look at numerical example from [1] in which Model (I) has been considered to analyze the system performance of bulk cargo terminal in Smederevo (city at Danube river in Serbia) in the context of nonstationary work order of the ASB link in the port for a long period of time. Because the given models have been developed for analysis of the real system (new bulk cargo terminal in Smederevo has been redesigned in 2005 and two new gantries were installed to unload the ore crude materials from barges into trucks), the nonstationary and stationary models, as well as its influence on the characteristics of the system, will be evaluated for the real states of the unloading terminal. The current capacity of the bulk cargo terminal is 2.4 million tons. The plan is to enlarge capacity of the bulk cargo terminal in order to satisfy the increased needs of production for ore crude materials. The purpose of giving models is to show the power of this methodology especially with respect to the various form of number of vessels in a batch distribution. The intent is to show how these models can be used to port performance evaluation.

Duration times of the nonstationary and stationary regimes were defined for the following parameters of the system: the number of berths $n = 3$, the number of areas in the waiting queue (anchorage size) $m = 36$, and the number of units in a group is given as the $M^X/M/2/12$ queue in Figure 5(a). As can be seen in Figure 5(a), blocking probabilities asymptotically approach to zero when the number of waiting areas increase ($m = 30$).

Figure 5(b) shows $P_B$, $P_V^{(1)}$ and $P_V^{(2)}$ as a function of anchorage size ($\theta = 0.92$ and $\bar{a} = 6$) for the $M^X/M/2/12$ queue.
a random variable $X$ under geometric and shifted Poisson distributions in accordance with systems (3.1) and (3.2), and the assumption is made that the system is empty at the beginning ($p_0(0) = 1, p_i(0) = 0$ for $i = 1, 2, 3, \ldots, 39, 40$). This does not diminish the generality of the conclusions.

The results of the analysis are presented in Figures 6, 7, and 8, and Table 2. Figure 6 presents the changes of operating parameters at ASB link in the river port for multiple server $(P_B, P_V^{(1)},$ and $P_V^{(2)}$, resp.) for the $M^X/M/3/36$ queue with geometric and shifted Poisson batch size distribution. The curves on Figure 6 are function of time ($t = 0–50$ h) with values $\lambda = 0.25$ and $\mu = 0.75$ and $\overline{a} = 6$. The characteristics of both models yield lower values of $P_B, P_V^{(1)},$ and $P_V^{(2)}$ for shifted Poisson batch size distribution than those on geometric distribution with the same parameters.

Furthermore, in Figures 7(a)–7(d), we have plotted $P_B, P_V^{(1)},$ and $P_V^{(2)}, N_w,$ and $t_w,$ respectively, as a function of traffic intensity ($\theta = 0–2$) with $\overline{a} = 6$. Clearly, the blocking probabilities are sensitive by orders of magnitude to the batch size parameters, so the characteristics of the input traffic must be carefully modelled. Geometrically distributed batches which have a high dispersion perform worse than the shifted Poisson distributed batches (see Figure 7(a)), except in the cases of short queues and high mean batch size, which may be attributed to the relatively large number of short batches from the geometric distribution as compared to the shifted Poisson for large mean batch size. This is due to the fact that for traffic intensity between 0.1 and 0.6 both models are similar under the same batch size distribution; see especially Figures 7(c) and 7(d).

Finally, in Figure 8 are shown $P_B, P_V^{(1)},$ and $P_V^{(2)}, N_w,$ and $t_w$ as a function of the anchorage size with the constant parameters ($\theta = 0.67$ and $\overline{a} = 6$) for the $M^X/M/3/36$ queue. There are several interesting observations as can be seen in Figures 8(a)–8(d). Considering different blocking models and various batch size distributions, we note that the batch blocking probability for Model (I) is smaller than $P_B$ for Model (II) up to $m = 32$. Also, $N_w$ and $t_w$ have lower values for Model (I) with geometric batch size distribution for $m < 32$. 

![Figure 6](image1.png)

Figure 6: Impact of the nonstationary work order on operating parameters’ changes: $P_B$ and $P_V$ as a function of $t$ for $M^X/M/3/36$ queue with different distribution of batch size.
As $m$ is increased above 32 each model for the same batch size distribution becomes constant with further increase of the anchorage size.

The results presented here support the argument that port operating parameters under the nonstationary working regime have been obtained in the same range as results from stationary state of the port system. Various curves from all figures as a function of constant values of traffic intensity ($\theta = 0.67$) and mean batch size ($\overline{a} = 6$) for both working regime present always very close results, as can be seen in Table 2. The attained agreement of the results obtained from Table 2 has been also used for validation and verification of considered models. In accordance with that, this correspondence between results gives, in full, the validity both models to be used for port performance evaluation.

5. Conclusions

Unlike previous studies, this paper is based on real river port systems were presented, and a significant improvement is demonstrated in the operational performance as a result of the $M^X/M/n/m$ queue. A real problem of dynamic system performance evaluation at a port has driven the development of these models. Closed-form expressions for state probabilities and blocking probabilities for the whole batch acceptance model are presented. As the problem gets complicated, a closed-form solution may not be possible to derive for the part batch acceptance model.

Contribution of this paper is twofold: analytical models development and analysis of dynamic performance measures and the blocking probability $P_B(t)$ for an arbitrary batch and the blocking probability $P_V(t)$ of an arbitrary vessel at the moment $t$ are expressed. It is evident that the influence of the nonstationary work order on operating parameters, expressed by the function $P_i(t)$, makes use of the queuing theory models to describe the operation of ASB link possible.

The results have revealed that analytical modelling is a very effective method to examine the impact of introducing priority, for certain class of vessels, on the ASB link performance and show that Model (I) has always lower batch blocking probability and has always higher blocking probability of an arbitrary vessel and hence lower vessel throughput. It was shown that this conclusion does depend on the different distribution of batch size too.
