Tracking a target in a cluttered environment is a representative application of sensor networks. In this paper, we develop a distributed approach to estimate the motion states of a target using noisy measurements. Our method consists of two parts. In first phase, using the unscented sigma-point transformation techniques and information filter framework, a class of algorithms denoted as unscented information filters was developed to estimate the states of a target to be tracked. These techniques exhibit robustness and accuracy of sigma-point filters for nonlinear dynamic inference while being as easily fused as the information filters. In the second phase, we proposed a novel consensus protocol which allows each sensor node to find a consistent estimate of the value of the target. Under this protocol, the final estimate of the value of the target at each time step is iteratively updated only by fusing the neighbors’ measurements when one sensor node is out of the measurement scope of the target. Performance of the distributed unscented information filter is demonstrated and discussed on a target tracking task.

1. Introduction

Recent advances in communication, computation, and embedded technologies support the development of mobile sensor networks (MSNs). The motivation behind MSNs is that they have broad applications including target tracking, cooperative detection of toxic chemicals in contaminated environments, search and rescuing operations after disasters, and forest fire monitoring [1–5]. One of the fundamental purposes of the sensor networks is to estimate and track the state of a process of interest using a large number of dispersed wireless sensors. This is partly because of the fact that multiple data sources can provide more complementary information that is not available by individual source; moreover, strong robust performance can be obtained because of the inherent redundancy [6]. To implement the sensor fusion, two questions are often encountered about what information should be communicated and how to fuse the received information. Many strategies have been proposed to resolve these problems, in which the Kalman filter is one of the most significant candidate. The sensor fusion architecture can be loosely categorized into three types, that is, the centralized fusion, the decentralized fusion, and the distributed fusion. In case of the centralized fusion [7], all the measurements are transmitted to a central processor, where a conventional Kalman filter or its counterpart is used to obtain the global state estimates. Although the centralized architecture is theoretically optimal and it is also conceptually simple to implement, it suffers from some drawbacks, such as it needs a heavy computational cost and may require a large amount of energy for a high communication load. Furthermore, it is usually impossible to apply a centralized processor when the sensor networks are of large scale, and the fusion cannot be carried out if the central unit fails. Therefore, a natural way is to implement the sensor fusion in a decentralized architecture [8]. To be specific, a group of local Kalman filters is used in parallel to obtain sensor-based estimates. Then, the local estimates instead of measurements are transmitted to the fusion center. To avoid the requirement of a fusion center, a fully decentralized fusion filter has been proposed in [9]; however, this scheme requires every sensor to communicate with any other sensor node and it is not scalable for large-scale sensor networks. In other
words, the sensor networks should be fully connected, which might not be possible in practical applications. Due to these inherent limitations of centralized and decentralized fusion algorithms, developing distributed algorithms has been the subject of intensive studies by many researchers.

Based on the Kalman filter, many distributed estimation algorithms have recently been proposed. As one typical of these distributed estimation algorithms, Kalman consensus filter received considerable attention for its fast convergence, high estimation performance, and globally optimal estimates without the requirement of a fusion center. Spanos et al. [10] introduced consensus algorithms to the problem of target state estimation in MSNs; the algorithms proposed can be used to estimate the average value of all sensor inputs. Saber [11–13] established the framework of distributed Kalman filtering (DKF) algorithms and has done systematic researches on Kalman consensus filter. The essence of DKF is a networked multiagent system of communicating estimator agents. Each estimator is computationally implemented as an embedded microfilter module in a sensor. The main objective is to design the estimator of every sensor so that the distributed estimation problem is solved. Moreover, DKF is applicable to sensor networks with variable topologies and networks with packet loss. Even DKF algorithms that have been developed in the aforementioned references deal with the distributed estimation problems successfully; however, most of them assumed that the target model to be estimated is linear; moreover, they assumed that all the sensor nodes can measure the target. In this work, with the help of the sigma-point unscented transition approach, an unscented information filter (UIF) is proposed to cope with the nonlinear target models and this can be the first contribution of this paper.

2. Problem Statement and Preliminaries

2.1. Unscented Kalman Filtering at Local Processing Units.

Consider the following nonlinear Gaussian system:

\[ x(k+1) = f(x(k)) + w(k), \]

\[ z(k) = h(x(k)) + v(k), \]

where \( f(\cdot) \) is the state transition matrix and \( h(\cdot) \) is the measurement matrix. \( x(k) \in \mathbb{R}^n \) is the system's state vector, \( z(k) \in \mathbb{R}^m \) is the measurement, \( w(k) \in \mathbb{R}^r \) is a Gaussian process noise with the property that \( w(k) \sim N(0, Q(k)) \), and \( v(k) \in \mathbb{R}^m \) is a Gaussian measurement noise denoted as \( v(k) \sim N(0, R(k)) \).

The unscented Kalman filter (UKF) is a special case of sigma-point Kalman filters which uses the unscented transform for computing approximate solutions to the filtering problem of the system with form (1). Some basic operations performed in the UKF algorithm are summarized as follows [17].

\[ \xi_{0}^{i}[k-1 | k-1] = \tilde{x}[k-1 | k-1], \]

\[ \xi_{i}^{i}[k-1 | k-1] = \tilde{x}[k-1 | k-1] + \left[ \sqrt{(n+\lambda)} P[k-1 | k-1] \right], \]

\[ \xi_{i}^{i}[k-1 | k-1] = \tilde{x}[k-1 | k-1] - \left[ \sqrt{(n+\lambda)} P[k-1 | k-1] \right], \]

where \( i = 1, \ldots, n \)

and the associate weights are computed as:

\[ \omega_{0}^{m} = \frac{\lambda}{n+\lambda}, \]

\[ \omega_{i}^{m} = \frac{\lambda}{n+\lambda}(1-\alpha^{2}\beta), \]

\[ \omega_{i}^{m} = \frac{1}{2(n+\lambda)} \]

where \( i = 1, 2, \ldots, 2n \), \( \lambda = \alpha^{2}(n+\kappa) - n \) is a scaling parameter, while \( \alpha \), \( \beta \), and \( \kappa \) are constant parameters.
Taking each of the sigma points according to system (1) to compute the predicted state \( \hat{x}[k | k-1] \) and the predicted covariance \( P[k | k-1] \) as
\[
\xi^i[k | k] = f(\xi^i[k-1 | k-1]), \quad i = 0, 1, \ldots, 2n,
\]
\[
\tilde{x}[k | k-1] = \sum_{i=0}^{2n} \omega^m_i \xi^i[k | k],
\]
\[
P[k | k-1] = \sum_{i=0}^{2n} \omega^c_i [\xi^i[k | k] - \tilde{x}[k | k-1]] ^T + Q[k-1].
\]
(4)
(5) Select the new predicted sigma point as \( \hat{x}[k | k-1] \) and \( P[k | k-1] \) to compute the propagation of state \( x[k | k] \)
\[
\eta^0_k = \tilde{x}[k | k-1],
\]
\[
\eta^i_k = \tilde{x}[k | k-1] + \sqrt{(n+\lambda)P[k | k-1]}, \quad i = 1, \ldots, n,
\]
\[
\eta^i_k = \tilde{x}[k | k-1] - \sqrt{(n+\lambda)P[k | k-1]}, \quad i = n+1, \ldots, 2n.
\]
(6)
(7) Compute the predicted \( \tilde{z}[k | k-1] \), covariance of the measurement \( P_{xz}[k] \), and the cross covariance of the state and measurement \( P_{xx}[k] \)
\[
\zeta^i_k = h(\eta^i_k), \quad i = 0, 1, \ldots, 2n,
\]
\[
\tilde{z}[k | k-1] = \sum_{i=0}^{2n} \omega^m_i \zeta^i_k,
\]
\[
P_{xz}[k] = \sum_{i=0}^{2n} \omega^c_i \left[ \zeta^i_k - \tilde{z}[k | k-1] \right] ^T \left[ \zeta^i_k - \tilde{z}[k | k-1] \right] + R[k-1],
\]
\[
P_{xx}[k] = \sum_{i=0}^{2n} \omega^c_i \left[ \eta^i_k - \tilde{x}[k | k-1] \right] ^T \left[ \zeta^i_k - \tilde{z}[k | k-1] \right].
\]
(8)
(9) Update the filter gain \( K_k \) and the state \( \tilde{x}[k | k] \), the covariance \( P[k | k] \), conditional to the new measurement \( z[k] \)
\[
\tilde{x}[k | k] = \tilde{x}[k | k-1] + K_k (z[k] - \tilde{z}[k | k-1])
\]
\[
K_k = P_{xz}[k] P_{zz}[k]^{-1}
\]
\[
P[k | k] = P[k | k-1] - K_k P_{xz}[k] K_k ^T.
\]
(10) \( i[k] = H^T[k] R[k]^{-1} z[k] \)
(11) \( I[k] = H^T[k] R[k]^{-1} H[k] \).
(12) For a linear discrete time model \( x[k+1] = A[k-1] x[k-1] + w(k-1) \) and the measurement model \( z[k] = H[k] x[k] + v[k] \), where \( A[k-1] \) is the state transition matrix, \( H[k] \) is the measurement matrix and \( w[k], v[k] \) with the same meanings defined in (1). With the aforementioned definitions defined in (9), (10), and (11), the recursive equations of the information form of the Kalman filter can be written as follows [9].
(1) Prediction:
\[
Y [k | k-1] = \left[ A[k-1] Y^{-1}[k-1 | k-1] A^T \right] ^{-1} \times [k-1] + Q[k-1]^{-1}
\]
\[
\tilde{y}[k | k-1] = Y [k | k-1] A[k-1] Y^{-1}[k-1 | k-1] \times [k | k-1] \tilde{y}[k-1 | k-1].
\]
(2) Updating:
\[
Y [k | k] = Y [k | k-1] + I[k]
\]
\[
\tilde{y}[k | k] = \tilde{y}[k | k-1] + i[k].
\]
Just like the classical Kalman filters, the basic information filters can only be used for linear system models. To deal with the filter problems of nonlinear system (1), we can use unscented transformation to replace $A[k−1]$ and $H[k]$ in the linear model. The unscented information filter (UIF), which is derived by embedding a statistical linear error propagation approach based on the unscented transformation into the information filter structure, will be proposed and presented in this subsection.

As for the unscented transformation, the prediction of information filter can be rewritten as

$$Y[k | k−1] = P^{−1}[k | k−1]$$

$$\tilde{y}[k | k−1] = Y[k | k−1] \sum_{i=0}^{2n} w_i^m \xi [k | k],$$

where $\xi [k | k]$ and $P[k | k−1]$ are defined in (4). Because we did not have the accurate linearized measurement matrix $H[k]$, we cannot calculate the information contribution defined by (10) and (11). Instead, it is assumed that the nonlinear measurement equation of the system in (1) can be mapped into a linear function of its statistical such as mean and covariance, which makes it possible to use the information update equations of the information filter. By this assumption, the observation covariance and its cross-correlation matrix are approximated by

$$P_{xz} [k] = E [(\varepsilon[k] − \bar{\varepsilon} [k | k−1]) (\varepsilon[k] − \bar{\varepsilon} [k | k−1])^T]$$

$$= H[k] P[k | k−1] H^T [k]$$

$$P_{xx} [k] = E [(\varepsilon [k] − \bar{\varepsilon} [k | k−1]) (\varepsilon [k] − \bar{\varepsilon} [k | k−1])^T]$$

$$= P[k | k−1] H^T [k],$$

and $H[k]$ is the Jacobian of the output equation $h(x[k])$. Nextly, multiplying the predicted covariance and its inverse term on the right side of the information matrix and replacing $P[k | k−1] H^T [k]$ with $P_{xz}[k]$ give the following representation of the information matrix:

$$I[k] = H^T [k] R^{-1}[k] H[k]$$

$$= P^{−1} [k | k−1] P[k | k−1] H^T [k] R^{-1}[k]$$

$$\times [k] H[k] P^T [k | k−1] P^{−T}[k | k−1]$$

$$= P^{−1} [k | k−1] P_{xz}[k] R^{-1}[k] P_{xz}^T [k] P^{−T}[k | k−1],$$

(16)

where $P[k | k−1]$ is calculated according to (4) and the cross-correlation matrix $P_{xz}[k]$ is calculated from (6). Similarly, the information state vector $i[k]$ can be rewritten as

$$i[k] = H^T [k] R^{-1}[k] \{v[k] + H[k] \bar{\varepsilon}[k | k−1]\}$$

$$= P^{−1} [k | k−1] P[k | k−1] H^T [k] R^{-1}[k]$$

$$\times \{v[k] + H[k] P^T [k | k−1] P^{−T}[k | k−1]\}$$

$$= P^{−1} [k | k−1] P_{xz}[k] R^{-1}[k]$$

$$\times \{v[k] + P_{xz}^T [k] P^{−T}[k | k−1] \bar{\varepsilon}[k | k−1]\}.\tag{17}$$

From (16) and (17), we can find that the information contribution is no longer associated with the measurement equation directly. To complete the analogy to the information contribution equations of the information filter, a pseudo-measurement matrix is defined as

$$H^P[k] = P^{−1}[k | k−1] P_{xz}[k],\tag{18}$$

where $P_{xz}[k]$ is calculated from (6) with $\bar{\varepsilon}[k | k−1], \eta_k, \xi_k$ and $\bar{z}[k | k−1]$ being defined in (4), (5), and (6). In terms of the pseudo-measurement matrix $H^P[k]$, the information contributions equations are written as

$$I[k] = (H^P[k])^T R^{-1}[k] H^P[k]$$

$$i[k] = H^P[k] R^{-1}[k] \{v[k] + (H^P[k])^T \bar{\varepsilon}[k | k−1]\}.\tag{19}$$

Up to now, we can reach at the prediction and updating procedures of unscented information filter using (14) and (19).

2.3. Distributed Fusion Based on UIF. Consider a sensor network with an ad hoc topology $\mathcal{G}$ that consists of a node set $\mathcal{V} = \{s_1, s_2, \ldots, s_n\}$ and an edge set $\mathcal{E} \subseteq \mathcal{V} \times \mathcal{V}$. The set $\mathcal{V}$ consists of $n$ vertices representing the sensors that belong to a finite set $1$; an edge of $\mathcal{G}$ is denoted by $e_{ij} = (s_j, s_i) \in \mathcal{E}$, which consists of unordered pairs of distinct vertices of $\mathcal{G}$ and represents available communication links. The set of neighbors of sensor node $s_i$ is denoted by $\mathcal{N}_i = \{s_j \in \mathcal{V} : (s_i, s_j) \in \mathcal{E}\}$. A path is a sequence of ordered edges of the form $(s_{i_1}, s_{i_2}, s_{i_3}, \ldots, s_{i_{j−1}}, s_j)$, where $j \in \mathbb{N}$ and $s_j \in \mathcal{V}$ and we called $j$ as the length of the path. If $s_{i_k} = s_j$, then the path is called a cycle; if $j = 1$, that is, an edge from it to itself, it is called a loop. The adjacent matrix $\mathcal{A} = [a_{ij}] \in \mathbb{R}^{\mathcal{E} \times \mathcal{E}}$ is defined such that $a_{ij} = a_{ji} = 0$ if $(s_i, s_j) \in \mathcal{E}$, while $a_{ij} = 0$, otherwise. Note that $\mathcal{A}$ is symmetric. The Laplacian matrix $\mathcal{L} = [\ell_{ij}] \in \mathbb{R}^{\mathcal{E} \times \mathcal{E}}$ associated with $\mathcal{A}$ can be defined as $\ell_{ii} = \sum_{j=1, j \neq i} a_{ij}$ and $\ell_{ij} = -a_{ij}$, where $i \neq j$. Note that $\mathcal{L}$ is symmetric positive. In addition, 0 is a simple eigenvalue of $\mathcal{L}$ with the associated eigenvector $\mathbf{1}$, and all other eigenvalues of $\mathcal{L}$ are positive if and only if graph $\mathcal{G}$ is connected.
The main advantage of the information filter over the Kalman filter in data fusion problems is the relative simplicity of the update stage and its simple extension to multisensor scenarios due to its characteristics of linear additivity. For a system with \( n \) sensors, the local UIF iterations for node \( i \) are in the form of

\[
Y_i[k | k] = Y_i[k | k-1] + I_i[k] + \sum_{j=1}^{y_i} I_{j}[k], \quad (20)
\]

\[
\hat{Y}_i[k | k] = \hat{Y}_i[k | k-1] + \hat{I}_i[k] + \sum_{j=1}^{y_i} \hat{I}_{j}[k].
\]

Our main problem here is to compute the averages of \( Y_i[k | k] \) and \( \hat{Y}_i[k | k] \) of all the sensors, which means to drive the information fusion of all the local sensors to a consensus state. With above notations, the main problems we concerned in this paper can be formalized as follows:

\[
\|Y_i[k | k] - Y_j[k | k]\| \to 0, \quad \forall i, j \in \{1, \ldots, n\},
\]

\[
\|\hat{Y}_i[k | k] - \hat{Y}_j[k | k]\| \to 0, \quad \forall i, j \in \{1, \ldots, n\}. \quad (21)
\]

If the local fusion of each node satisfies with (21), we call the fusion estimate algorithm as distributed estimation and we will seek for such distributed estimation algorithms in the following section.

3. Distributed Unscented Information Filtering Using Consensus Seeking

3.1. Distributed Consensus Based Information Fusion. Distributed consensus filtering algorithms have been proposed as important computational tools in [13–16] to make (21) be carried out in a distributed manner by every sensor node. In all these works, the scheme is to update the state of each node according to some weighted linear combination of its own and neighbors’ states; however, we know that during the movement of the sensor nodes, the relative distance between sensor nodes and target may change; hence, the target may be out of measurement scope of the sensor node and therefore sensor nodes’ own information may not be available. To make the algorithms proposed in the aforementioned references be used when one sensor node is out of the scope of measurement, we propose a novel distributed linear iterations with the following form:

\[
\zeta^k[i+1] = \frac{1}{\sigma_i[i]} \frac{\zeta_i[k]}{a_i[k]} + \sum_{j=1, j \neq i} a_{ij}[k] \zeta_j[k], \quad \sigma_i[i] = 1,
\]

\[
= \left\{ \begin{array}{ll}
\frac{a_i[i]}{\sigma_i[i]} + \sum_{j=1, j \neq i} a_{ij}[k] \zeta_j[k], & \sigma_i[i] = 1, \\
0, & \sigma_i[i] = 0.
\end{array} \right. \quad (22)
\]

If the \( i \)th sensor can measure the target at time step \( k \), then \( \sigma_i[i] = 1 \), otherwise, \( \sigma_i[i] = 0 \). In the following subsection, we will analyze the convergence of (22) to deal with the main problem (21) we concerned.

3.2. Convergence Analysis. The matrix form of (22) can be written as

\[
\zeta^k[i+1] = D[i] \zeta^k[i],
\]

where \( \zeta^k = \left[ \zeta^k_1, \zeta^k_2, \ldots, \zeta^k_n \right]^T \) and \( D[i] = [d_{ij}] \in R^{n}, (i, j) \in \{1, \ldots, n\} \), with

\[
d_{ij} = \left\{ \begin{array}{ll}
\frac{a_i[i]}{\sigma_i[i]} + \sum_{j=1, j \neq i} a_{ij}[k] \zeta_j[k], & \sigma_i[i] = 1, \\
0, & \sigma_i[i] = 0.
\end{array} \right. \quad (24)
\]

It can be seen that \( D[i] \) is a stochastic matrix. Before going on, the following lemmas will be used.

Lemma 1 (see [18]). A nonnegative matrix \( A = [a_{ij}] \in R^n \) has the same positive constant row sum \( \mu > 0 \), namely,

\[
\sum_{j=1}^{n} a_{ij} = \mu, \quad i = 1, 2, \ldots, n. \quad (25)
\]

Then \( \mu \) is an eigenvalue of \( A \) with an associated eigenvector \( \mathbf{1} \) and \( p(A) = \mu \), where \( p(\cdot) \) denotes the spectral radius. In addition, the eigenvalue \( \mu \) of \( A \) has algebraic multiplicity equal to one, if and only if the graph associated with \( A \) has a spanning tree. Furthermore, if the graph associated with \( A \) has a spanning tree and

\[
a_{ii} > 0, \quad i = 1, 2, \ldots, n, \quad (26)
\]

then \( \mu \) is the unique eigenvalue of maximum modulus.

Lemma 2 (see [19]). Let \( A \in R^n \) be nonnegative and irreducible, and let \( \{s_{i}\} \) denote the set of vertices of the directed graph \( \Gamma(A) \). Denote by \( L_i = \{0, \ldots, l_i\} \) the set of lengths of all directed paths in \( \Gamma(A) \) that both start and end at the vertex \( s_{i} \), \( i = 1, 2, \ldots, n \). Denote by \( g_{i} \) the greatest common divisor of all the lengths in \( L_i \). Then, \( A \) is primitive if and only if all \( g_{i} = 1, i = 1, 2, \ldots, n \).

From Lemma 1, it can be seen that the condition in (26) is sufficient for \( \mu \) being the unique eigenvalue of maximum modulus. In the following lemma, we show that the condition in (26) can be relaxed.

Lemma 3. Suppose that a nonnegative matrix \( A = [a_{ij}] \in R^n \) has the same positive constant row sum \( \mu > 0 \). Then, \( \mu \) is the unique eigenvalue of maximum modulus if and only if either
(1) the graph $\Gamma(A)$ is strongly connected and all the lengths of cycles in $\Gamma(A)$ are coprime or (2) the graph $\Gamma(A)$ is not strongly connected but has a directed spanning tree, and at least one of the root vertices has a self-loop (an example is shown in Figure 1).

**Proof.** Consider two cases:

(i) if $\Gamma(A)$ is strongly connected, then by Lemma 1, $p(A) = \mu$. Furthermore, according to Lemma 2, it can be obtained that $\mu$ is the unique eigenvalue of maximum modulus, if and only if all the lengths of cycles in $\Gamma(A)$ are coprime;

(ii) if $\Gamma(A)$ is not strongly connected, Lemma 1 implies that $\mu$ is an eigenvalue of $A$ and $\mu$ has algebraic multiplicity equal to one, if and only if the graph $\Gamma(A)$ associated with $A$ has a spanning tree. In the following, we will show that if the condition assumed in (2) of Lemma 3 is satisfied, then there will be no other eigenvalues for $A$ with modulus $\mu$.

**Sufficiency.** By Geršgorin disc theorem, all the eigenvalues of $A$ are located in the union of $n$ discs given by

$$\bigcup_{j=1}^{n} \left\{ z \in \mathbb{C} : |z - a_{ij}| \leq R_j^* \right\} = \sum_{j=1, j \neq i}^{n} |a_{ij}|, \quad (27)$$

where $R_j^* \equiv \sum_{j=1, j \neq i}^{n} |a_{ij}|, 1 \leq i \leq n$ is called the deleted absolute row sums of $A$.

Without loss of generality, label the root vertex as vertex 1 and assume that $a_{11} > 0$; that is, it has a self-loop and the other diagonal entries of $A$ can be zero. By (27) and (25) and because $a_{11} > 0$, there are at most $n-1$ same discs centering at the origin and having radius $\mu$. When $a_{11} > 0$, it is obviously that $R_1^* < \mu$ and its disc is contained in the discs of radius $\mu$. As a result, all the eigenvalues of $A$ are in the discs of radius $\mu$ and there is only one intersection point on the right axis $x_0 = \mu$.

This can be shown by contradiction as follows. Assume that there exists a $\lambda^* = \mu \cos \theta + \omega \cdot \sin \theta$ which is different from $\mu$ such that $Ax^* = \lambda^* x^*$, $x^* = [x_i] \neq 0$, where $\omega$ is imaginary part. According to Geršgorin theorem, $|\lambda^*| = \mu$ implies that $\lambda^*$ is a boundary point of the discs with radius $\mu$. Suppose that $\delta$ is an index such that $|x_i| = \max_{j \in \mathbb{C}} |x_i| = \|x^*\|_\infty \neq 0$. When $\theta = 0$, it will be that $\lambda^* = x_0 = \mu$. As a result, $0 < \theta < 2\pi$. Due to $Ax = \lambda x$, we have

$$\left(\lambda - a_{ii}\right) x_i = \sum_{j=1, j \neq i}^{n} a_{ij} x_j, \quad i = 1, \ldots, n. \quad (28)$$

In terms of (28), we get

$$|\lambda - a_{ii}| \cdot |x_i| = \sum_{j=1, j \neq i}^{n} |a_{ij}| \cdot |x_j| \leq \sum_{j=1, j \neq i}^{n} |a_{ij}| \cdot |x_\delta| = R^*_j |x_\delta|. \quad (29)$$

Thus, on one hand, if $l$ is any index such that $x_l = |x_\delta|$, we must have $|\lambda - a_{ii}| \leq R^*_l$. On the other hand, we have to show that $\lambda^*$ is a point on the boundary of the discs with radius $\mu$, which means that $\lambda^*$ is not an interior point of any Geršgorin disc. Therefore, $|\lambda^* - a_{ii}| \geq R^*_l$. As a result, for $i = l$, we get

$$|\lambda^* - a_{ii}| \cdot |x_i| = \sum_{j=1, j \neq i}^{n} |a_{ij}| \cdot |x_j| \leq \sum_{j=1, j \neq i}^{n} |a_{ij}| \cdot |x_\delta| = R^*_j |x_\delta|, \quad (30)$$

which implies $|\lambda^* - a_{ii}| \cdot |x_i| = R^*_j |x_\delta|$. Since $|x_\delta| = \|x^*\|_\infty > 0$, we have $|\lambda^* - a_{ii}| \geq R^*_j$. This means that $\lambda^*$ is in the boundary of the $l$th disc. As a result, if $l$ is any index such that $x_l = |x_\delta|$, then $\lambda^*$ is in the boundary of the $l$th disc. According to (30), it follows that

$$\sum_{j=1, j \neq i}^{n} |a_{ij}| \left( |x_i| - |x_j| \right) = 0. \quad (31)$$

In (31), if $|a_{ij}| > 0$, then $|x_i| - |x_j| = 0$. As a result, $\lambda^*$ is in the boundary of $l$th disc. Because there exists at least one spanning tree in $\Gamma(A)$, then there is a directed path from the root vertex $v_1$ to any other vertices including the vertex $v_l$. Thus, a path $(s_1, s_2, \ldots, s_l, s_j, \ldots, s_{l-1}, s_j)$ with length $r$ exists, and all the corresponding weighting factors $|a_{j1}, a_{j2}, \ldots, a_{jr}|$ are greater than zero. Using (31), it follows that

$$x_j = x_{j1} = x_{j2} = \cdots = x_{jr} = x_j; \quad (32)$$

this means that $\lambda^*$ is in the boundary of the $l$th, $j$th, $j_2$th, $\ldots$, and the $j$th discs. But the radius of the $l$th disc is $\mu - a_{ii}$ which is smaller than $\mu$ and there is only one intersection point $x_0 = \mu$; see Figure 2. This is a contradiction. Thus, we have that $\lambda = \mu$ is the unique eigenvalue of maximum modulus. In addition,
due to the same sum row of $A$, it is can be derived that $x = 1$ is the right eigenvector corresponding to $\mu$.

**Necessity.** We prove this part by contraposition. Without loss of generality, we assume that there exists a spanning tree with vertex $s_i$ as its root with the property that it does not have a self-loop; that is, $(s_i, s_j) \notin \varepsilon$. Suppose that subgraph $\mathcal{G}'_i$ induced by $s_i, s_j, \ldots, s_k (1 \leq k \leq n)$ is the maximal-induced subgraph and itself is a cycle but all vertices in $\mathcal{G}'_i$ do not have self-loops. Let the vertices in $\mathcal{G}' - \{s_i, s_j, \ldots, s_k\}$ be $s_{k+1}, s_{k+2}, \ldots, s_n$. Then, there exists a permutation matrix $P$ such that

$$PBP^{-1} = \begin{bmatrix} B_{11} & B_{12} \\ B_{21} & B_{22} \end{bmatrix},$$

where $B = A - \mu I_n$ and

$$B_{11} = \begin{bmatrix} b_{s_1s_1} & \cdots & b_{s_1s_k} \\ \vdots & \ddots & \vdots \\ b_{s_k s_1} & \cdots & b_{s_k s_k} \end{bmatrix},$$

$$B_{12} = \begin{bmatrix} b_{s_1s_{k+1}} & \cdots & b_{s_1s_n} \\ \vdots & \ddots & \vdots \\ b_{s_{k+1}s_1} & \cdots & b_{s_{k+1}s_n} \end{bmatrix},$$

$$B_{21} = \begin{bmatrix} b_{s_{k+1}s_{k+1}} & \cdots & b_{s_{k+1}s_k} \\ \vdots & \ddots & \vdots \\ b_{s_k s_{k+1}} & \cdots & b_{s_k s_n} \end{bmatrix},$$

$$B_{22} = \begin{bmatrix} b_{s_{k+2}s_{k+2}} & \cdots & b_{s_{k+2}s_k} \\ \vdots & \ddots & \vdots \\ b_{s_k s_{k+2}} & \cdots & b_{s_k s_n} \end{bmatrix}.$$ \hspace{1cm} (32)

Since $\mathcal{G}'_i$ is maximal, then $B_{12} = 0$. Furthermore, $\mathcal{G}'_i$ is itself a cycle without self-loops, so all diagonal entries of $B_{11}$ are zeros and zero is one eigenvalue of it. Consider that $\Gamma(A)$ has a spanning tree, which means that zero is one eigenvalue of $B_{22}$. Thus, we know that $B$ has at least two zero eigenvalues, which in turn implies that $A$ has more than one eigenvalue equal to $\mu$, which contradicts the assumption. Thus, there must be at least one vertex in $\mathcal{G}'_i$ that has a self-loop. This completes the proof.

**Remark 4.** From Lemma 3, it can be seen that if $\Gamma(A)$ is not strongly connected, then at least one of the root vertices has a self-loop to ensure $\mu$ being the unique eigenvalue with maximum modulus. On the other hand, if $\Gamma(A)$ is strongly connected, the existence of a self-loop is not necessary, but one vertex having a self-loop is sufficient to guarantee $\mu$ being the unique eigenvalue with maximum modulus. If the graph is strongly connected, then there must be a cycle including all the $n$ vertices; that is, a cycle of length $n$ exists for every vertex. Furthermore, if there is a vertex having a self-loop, then the cycle of length $1$ exists and it is called a trivial cycle. As a result, the cycles of lengths $n$ (not passing the loop) and $n + 1$ (passing the loop) exist for every vertex. Since $n$ and $n + 1$ are coprime, by Lemma 2, we have $A$ as primitive. If there are $d$ loops $(1 \leq d < n)$ in $\Gamma(A)$, then there are $d$ positive diagonal entries in $A$, which means that the cycles of length $1$ exist. Using the same discussion above, we have $A$ as primitive. In particular, if each vertex has a self-loop, then the result in Lemma 3 reduces to that in [18] (Figure 3).

Based on Lemma 3, the necessary and sufficient conditions on guaranteeing consensus using the designed protocol results are summarized in Theorem 5.

**Theorem 5.** Let $\mathcal{G}$ be a fixed interaction topology of a sensor networks. If and only if either (1) $\mathcal{G}$ is strongly connected and all the lengths of cycles in $\mathcal{G}$ are coprime (2) or the graph $\mathcal{G}$ is not strongly connected but has a directed spanning tree and the root vertices (i.e., vertices have directed paths to all other vertices) exist and at least one of them has a self-loop, then the problem
we concerned can be solved asymptotically by using the novel protocol (22).

Proof. When the graph \(\mathcal{G}\) is not strongly connected consider the following.

(i) Sufficiency. In (23), the update matrix \(D\) corresponding to \(\mathcal{G}\) is fixed, and we have

\[
\eta^k [l+1] = D \eta^k [l], \quad l = 0, 1, 2, \ldots
\]

Since \(D\) is a stochastic matrix, by Lemma 3, \(\mu = 1\) is the unique eigenvalue of maximum modulus. It can be obtained that \(D\) is indecomposable and aperiodic (SIA). As a result, there is a constant vector such that

\[
\lim_{l \to \infty} \eta^k [l+1] = \lim_{l \to \infty} D^m \eta^k [0] = 1 \cdot \eta^0.
\]

Thus, the consensus is achieved.

(ii) Necessity. If the root vertex has no self-loop, according to Lemma 3, \(\mu = 1\) is the unique eigenvalue of maximum modulus and consensus cannot be achieved. When the graph \(\mathcal{G}\) is strongly connected, if and only if all the lengths of cycles in \(\mathcal{G}\) are coprime, and \(\mu = 1\) is the unique eigenvalue of maximum modulus. Under this condition, the distributed estimation can be achieved by following the similar analysis of the above discussion. The proof is completed.

\[\Box\]

4. Simulation Results

Consider a target with dynamics

\[
\mathbf{x}(k) = \Phi \mathbf{x}(k - 1) + \Gamma \omega(k)
\]

with

\[
\Phi = \begin{bmatrix}
1 & T & 0 & 0 \\
0 & 1 & 0 & 0 \\
0 & 0 & 1 & T \\
0 & 0 & 0 & 1 \\
\end{bmatrix},
\]

\[
\Gamma = \begin{bmatrix}
T^2 & 0 \\
\frac{T^2}{2} & 0 \\
0 & T^2 \\
0 & \frac{T^2}{2} \\
\end{bmatrix},
\]

where \(T = 1\) s is the sampling interval and \(\omega[k]\) is the corresponding Gaussian motion noise with covariance \(Q[k] = (1e - 3) \ast \text{diag}[0.5\text{ m/s}^2, 1\text{ m/s}^2]\), while \(\mathbf{x}[k] = [x[k], \dot{x}[k], y[k], \dot{y}[k]]\) represents the coordinates and the velocities.

A sensor network with three located nodes is used in this simulation (see Figure 4). The nodes make noisy measurement of the distance between target and observing station; that is

\[
z_i(k) = \sqrt{(x_i(k) - x_0)^2 + (y_i(k) - y_0)^2} + v_i(k),
\]

where \(z_i[k]\) is the observed range by \(i\)th node and \(v_i[k]\) is the corresponding Gaussian measurement noise with covariance \(R[k] = 5\text{ m}. (x_0, y_0) = [200; 300]\) is the position of observing station. The initial state of the target is \([0\text{ m}; 2\text{ m/s}; 200\text{ m}; 20\text{ m/s}]\).

Figure 5 shows the truth target trajectory and actual trajectories of the sensor nodes. It can be seen that all the trajectories estimated by the algorithm proposed have good tracking performance for the truth target trajectory. Figure 6 depicts a comparison of root mean square errors (RMSEs) of target position estimation error of each nodes; it can be seen that the target position estimation RMSEs of all nodes are as low as to zero. The consecutive snapshots of errors of target position estimation in \(x\)-axis and \(y\)-axis between each node are depicted in Figures 7 and 8; it demonstrates that the estimates by each node can reach consensus states ultimately. Considering the fact that the centralized algorithms are optimal theoretically, we compared the RMSE of target position estimation error between each sensor node and the centralized algorithm in Figure 9. It can be seen that the estimated error of each node is as low as to the centralized algorithm, which shows that the distributed unscented information filter proposed has good performance for tracking the target coordinate in sensor networks.

5. Conclusions

A novel consensus-based distributed unscented information filter for mobile sensor networks is presented in this work, which integrates the unscented information filter and consensus algorithm, as well as a new framework for the consideration of one sensor node being out of the measurement scope of the target to be tracked. A target tracking application by
three sensor nodes is employed to illustrate the performance of the proposed algorithm. The simulation results show that the algorithm proposed can be used to coordinated target tracking scenes in sensor networks. As we know, the fusion techniques are only tools being used to process the measured date; however, the quality of the sensed date is the key for the filter algorithm, so how to use the estimated date to drive the sensor nodes coordinately to get high quality dates is important and this could be our ongoing works. Furthermore, issues revolving communication problems among sensor nodes such as switching topologies (time-varying network topologies) and time delays pose many challenging problems that warrant further research.
