Usually, when parameter identification is applied, there are some gains related to the identification algorithm whose value must be carefully adjusted in order to obtain a good performance of the algorithm. However, when performing closed loop identification, there are some other constants that in general are not taken into account for the identification algorithm: the controller gains, which may appear inside the identification algorithm, specifically in the regressor vector, which is very important for the parameter convergence according to the persistence of excitation condition. Therefore, the effect of these gains on the estimated parameters should be analyzed so that better estimates can be obtained. This paper addresses the behavior of the parameter estimates for a closed-loop identification methodology applied to a DC servomechanism with a bounded perturbation signal and a PD controller. It is shown that, with this perturbation, the parameter estimates converge to a region whose size can be modified not only by varying the identification algorithm gains but also by modifying the P and D controller gains in a suitable way.

1. Introduction

It is well known that servomechanisms are fundamental in modern robotic and mechatronic systems for industrial applications where high speed and high precision are of prime importance. On the other hand, in order to apply model-based tuning methods it is necessary to apply an identification algorithm to the servomechanism and, if it is required, to design a high performance controller where a small steady state tracking error and high precision are necessary. Besides, the system parameters are also important to know if the system itself behaves as it should, for example, by evaluating its performance with some specified test signals. Thus, parameter identification plays a very important role for designing a controller as pointed out from several points of view [1–4].

For a DC servomechanism, there are several techniques that may be applied for identifying its parameters, when the servomechanism operates in open loop and in closed loop. However, it is important to note that if the variable of interest is the servo position, then a linear model of a servomechanism contains a pole on the imaginary axis, thus making the system not BIBO stable, that is, a bounded input applied to the servomechanism would not produce a bounded position and this may lead to undesired effects, for example, in robotic applications. Therefore, for security reasons, parameter identification should be performed in closed loop.

One way to characterize the system identification algorithms is [5, 6] (i) direct methods and (ii) indirect methods. Many of the identification procedures using a linear controller [7–9] fall into the category of direct methods; that is, the parameter identification procedures are applied without regard to the controller being used to close the loop. On the other hand, if a technique takes into account the controller structure, then it falls into the category of indirect methods.

As mentioned before, for security reason it is better to estimate the system parameters with the system working in closed loop. One way to perform closed loop parameter identification of a servomechanism is with the relay-based techniques [10–12], which are widespread for servo identification. The idea with this methodology is to close the loop...
through a relay in order to obtain a sustained oscillation and then the values of the frequency and amplitude allows identifying a model of the system. The relay based techniques may work well; however, the reference signal used for exciting the system becomes constant in many time instants, and then no control is being applied in that time and then the effect of the disturbances may affect the estimates obtained with this methodology. Besides, tuning of the relay controller can be cumbersome and no one of the reviewed methods takes explicitly into account the disturbances affecting the servomechanism.

References [7–9, 13–15] propose methods for closed loop identification of position-controlled servos where the loop is closed using a linear controller. The approach proposed in [13, 14] uses a PD controller to close the loop and an on-line gradient algorithm allows estimating a linear and nonlinear model of a servomechanism. Also, in [15] a two-step identification method for estimating the four parameters of a nonlinear model of a position control servomechanism is presented, where the proposed identification scheme relies on the theory of operational calculus. However, the effect of perturbations is considered only for constant values. On the other hand, a common technique used for identifying DC servomechanisms is based on the least squares algorithm. In [16], an approach for identifying a DC motor is presented considering the Coulomb friction and dead zone using a recursive discrete time least squares algorithm with forgetting factor using a Hammerstein model for the motor. In [17], second-order sliding modes approach is applied for estimating the parameters of a DC motor operating in open-loop and closed loop, while in [18] the inertia of a second-order model of a DC servomechanism driving a human assistive system is identified using Bode plots obtained from input-output measurements. Finally, another interesting approach is presented in [2, 4], where an online algebraic identification method is proposed. Besides, [19, 20] show how this methodology can be used for parameter identification of a DC motor and also this methodology was used and modified in [21] introducing a batch least squares algorithm for estimating the parameters of an induction motor.

All the previous works consider in general the importance of some gains related with the identification algorithm for closed-loop identification. However, in some cases (as that presented in [13, 14]) the controller gains get involved in with some important elements for the identification scheme, for example, in the regressor vector. In this case, it has not been analyzed which effect actually has such gains in the parameter identification procedure and how the parameter estimates will behave when a disturbance is affecting the system. Then, this work presents the analysis of a closed loop identification algorithm for a perturbed position-controlled DC servomechanism where a PD controller closes the loop and achieves stability without knowledge about the servomechanism parameters. Theoretical results show that, when the perturbation signal is identically zero, exponential convergence can be claimed, and in the presence of a bounded perturbation it is possible to obtain a region $\Omega_\delta$ the parameter estimates belong. What’s more, it will be shown that this region can be made arbitrarily small if the controller gains are tuned properly. Some simulations depict the behavior of the region $\Omega_\delta$, showing the effect that the controller gains have on the estimated parameters.

The paper is organized as follows. Section 2 is devoted to present preliminary theoretical results of passivity based control, adaptive control, and the general description of the DC servomechanism. Section 3 presents the analysis for closed loop identification of the servomechanism when no disturbances are affecting the system and the exponential stability of the overall identification scheme is shown. Section 4 extends the analysis for the perturbed case and Section 5 deals with the analysis of the results. Finally, Section 6 gives some concluding remarks.

2. Preliminary Results

The closed loop identification analysis that will be presented is based on some results related with passivity theory and adaptive control, and thus the following results are worth presenting.

2.1. Passivity and Adaptive Control. As pointed out before, the aim of this work is to show the convergence properties of the identification algorithm with respect to the value of the controller gains. To this end it will be necessary to use the observability property given in [22] and some results of passivity and stability that will be described in the following.

Let us consider the linear time-varying system

$[C(t), A(t)]$ defined by

$$
\begin{align*}
\dot{x} &= A(t)x(t), \\
y(t) &= C(t)x(t),
\end{align*}
$$

where $x(t) \in \mathbb{R}^n$, $y(t) \in \mathbb{R}^m$, while $A(t) \in \mathbb{R}^{m \times n}$ and $C(t) \in \mathbb{R}^{m \times n}$ are piecewise continuous functions. A system $[C(t), A(t)]$ is said to be uniformly completely observable (UCO) [22] if there exist strictly positive constants $[\beta_1, \beta_2, \delta]$ such that, for all $t_0 \geq 0$, $\beta_1 \leq N(t_0, t_0 + \delta) \leq \beta_2 I$, where $N(t_0, t_0 + \delta) \in \mathbb{R}^{m \times n}$ is the so-called observability Gramian as

$$
N \left( t_0, t_0 + \delta \right) = \int_{t_0}^{t_0 + \delta} \Phi^T(r, t_0) C^T(r) C(r) \Phi(r, t_0) \, dr,
$$

where $\Phi(r, t_0)$ is the state transition matrix associated with $A(t)$. Now, assume that, for all $\delta > 0$, there exists $k_0 > 0$ such that, for all $t_0 \geq 0$, $\int_{t_0}^{t_0 + \delta} \|K(r)\|^2 \, dr \leq k_0$, where the matrix $K$ corresponds to the system under output injection as

$$
\dot{w} = \left[ A(t) + K(t) C(t) \right] w(t),
$$

$$
z(t) = C(t) w(t),
$$

with $w(t) \in \mathbb{R}^n$, $K(t) \in \mathbb{R}^{m \times n}$, and $z(t) \in \mathbb{R}^m$. Then, the system $[C, A]$ is UCO if and only if $[C, A + KC]$ is UCO, where the term $KC$ stands for the output injection term as indicated in [22]. Moreover, if the observability Gramian of the system $[C, A]$ satisfies the previous upper and lower bounds on $N$, then no control is being applied in that time and the system becomes constant in many time instants, and then the effect of the disturbances may affect the estimates obtained with this methodology. Besides, tuning of the relay controller can be cumbersome and no one of the reviewed methods takes explicitly into account the disturbances affecting the servomechanism.
then the observability Gramian of the system \([C, A + KC]\) satisfies these inequalities with identical \(\delta\) and

\[
\beta_1 = \frac{\beta_1}{1 + \sqrt{\delta}} \quad \beta_2 = \beta_2 \exp(k_0 \beta_2). \tag{4}
\]

Now assume that \(f(t,x) : R^n \times R^n \rightarrow R^n\) has continuous and bounded first partial derivatives in \(x(t)\) and is piecewise continuous in \(t\) for all \(x \in B_h, t \geq 0\).
Then, the following statements are equivalent [22]:

1. \(x = 0\) is an exponentially stable equilibrium point of \(\dot{x} = f(t,x), x(t_0) = x_0\).
2. There exists a function \(V(t,x)\) and some strictly positive constants \(\alpha_1, \alpha_2, \alpha_3, \delta\) such that, for all \(x \in B_h\) and \(t \geq 0\),
   \[
   \alpha_1 \|x\|^2 \leq V(t,x) \leq \alpha_3 \|x\|^2, \quad \dot{V}(t,x)_{x=f(t,x)} = -\alpha_3 \|x\|^2, \quad \|\partial V(t,x)/\partial x\| \leq \alpha_4 \|x\|.
   \]

Now, if there exists a function \(V(t,x)\) and strictly positive constants \(\alpha_1, \alpha_2, \alpha_3, \delta\) such that, for all \(x \in \mathbb{B}_h\)
and bounded first partial derivatives in \(L^n\),
   \[
   \dot{V}(t,x)_{x=f(t,x)} \leq -\alpha_3 \|x\|^2 \quad \text{then, } x(t) \text{ converges exponentially to zero.}
   \]

Finally, the state equation \([A, B, C, D]\) is a minimal realization of a proper rational function \(\tilde{g}(s)\) if and only if \((A, B)\) is controllable, \((A, C)\) is observable, or if and only if \(\det(\tilde{g}(s)) = 0\),
where \(\tilde{g}(s) = N(s)/D(s)\) and \(\deg(\tilde{g}(s)) = \deg(D(s))\).

In the next definitions, let us consider the system \(\Pi\) defined as

\[
\Pi : \begin{cases}
\dot{x}(t) = f(x, u), \\
x(0) = x_0 \in R^n, \\
y(t) = H(x(t), u),
\end{cases} \tag{5}
\]

where \(x \in R^n\) is the state vector, \(u \in R^m\) the input, and \(y \in R^m\) the system output. Consider the set \(\mathbb{X}\) of \(n\) dimensional real valued functions \(f(t) : R^n \rightarrow R^n\) and define the set

\[
L_2 = \{x \in \mathbb{X} : \|f(t)\|^2_{L^2} = \int_0^T \|f(t)\|^2 \, dt < \infty\},
\]

where \(\|\cdot\|\) is the Euclidean norm. This set constitutes a normed vector space with the field \(R\) and norm \(\|\cdot\|\).

Let \(x = 0\) be an equilibrium point of \(A, B, C, D\), that is, \(f(t) = 0\), \(y(t) = 0\) for all \(t \geq 0\).

The system \((5)\) is dissipative [24] with respect to the supply rate \(\omega(u, y) : R^m \times R^m \rightarrow R\) if and only if there exists a storage function: \(R_\omega \rightarrow R_{\gamma_0}\), such that \(H(x(T)) \leq H(x(0)) + \int_0^T \omega(u(t), y(t)) \, dt\), for all \(u(t)\), all \(T \geq 0\), and all \(x_0 \in R^n\).

Finally, if \(\omega(u, y) = \omega^\prime(y)\) then the system is passive if its supply rate is given by \((u, y) = u^\prime y\). It is input strictly passive (ISP) if there exists a positive constant \(\delta_1\) such that the supply rate can be expressed as \((u, y) = u^\prime y - \delta_1 \|u^\prime\|^2\), \(\delta_1 > 0\). Finally, it is output strictly passive (OSP) if there exists a positive constant \(\delta_2\) such that the supply rate can be expressed as \((u, y) = u^\prime y - \delta_2 \|y^\prime\|^2\), \(\delta_2 > 0\).

The system \((5)\) is called \(L_2\) finite gain stable if there exists a constant \(\gamma\) such that for any initial condition \(x_0\) there exists a finite constant \(\beta(x_0)\) such that \(\|y(T)\| \leq \|y(0)\| + \beta(x_0)\), and one important result from [24] is that if \(\Pi : u \rightarrow y\) is OSP, then it is \(L_2\) stable.

A state space system \(x(t) = f(x), x \in R^n\), is zero state observable from the output \(y(t) = h(x)\) if, for all initial conditions \(x(0) \in R^n\), the output \(y(t) \equiv 0\) implies that \(x(t) \equiv 0\). It is zero state detectable if \(y(t) \equiv 0\) implies that \(\lim(x(t)) = 0\) as \(t \rightarrow \infty\).

Regarding the identification algorithms, the persistence of excitation (PE) condition is very important and its definition is given now according to [22]: a vector \(\phi : R^n \rightarrow R^m\) is persistently exciting (PE) if there exist constants \(\{\alpha_1, \alpha_2, \delta\} > 0\) such that

\[
\alpha_1 I \leq \int_{t_0}^{t_0 + \delta} \phi(\tau) \phi^T(\tau) \, d\tau \leq \alpha_2 I, \quad \forall t_0 \geq 0. \tag{8}
\]

Besides, let \(w : R^n \rightarrow R^m\). If \(w\) is PE, the signals \(w, \dot{w}\) belong to the space \(L_{\infty}\), and \(U\) is a rational stable strictly proper minimum phase transfer function, then \(U(w)\) is PE.

**Theorem 1** (small signal I/O stability, [22]). Consider the perturbed system \(\dot{x} = f(t, x, u)\), \(x(0) = x_0\) and the unperturbed system \(x = f(t, x, 0)\), \(x(0) = x_0\), \(x \in R^n\), \(x(0) \in R^n\), \(u \in R^m\). Let \(f\) be piecewise continuous in \(t\) and have continuous and bounded first partial derivatives in \(x\) for all \(t \geq 0\), \(x \in R^n\), \(u \in R^m\). Let \(f\) be Lipchitz in \(u\), with Lipchitz constant \(L_{\phi}\) for all \(t \geq 0\), \(x \in R^n\), \(u \in R^m\).

The identification analysis that will be presented considers the model of a perturbed DC servomechanism described by the following equation:

\[
\ddot{y} + f\dot{y}(t) = ku(t) + v_1(t) = r(t) + v_1(t), \tag{9}
\]

where \(J, f, k, u, v_1\), and \(r(t) = ku(t)\) are the inertia, viscous friction coefficient, amplifier gain, input voltage, perturbation.
signal, and torque input, respectively. The perturbation signal may be due to possibly constant disturbances or parasitic voltages appearing inside the amplifier. The model (9) can be rewritten as
\[ \dot{q}v(t) = -a\dot{q}(t) + bu(t) + v(t), \]
where \( a = f/J \) and \( b = k/J \) are positive constants and \( v = v_1/J \) and \( \{q(t), \dot{q}(t)\} \) are the servo angular position and velocity, respectively. It is also assumed that the perturbation signal \( v(t) \) is bounded, that is:
\[ \|v(t)\| \leq \beta, \beta \in \mathbb{R}^+. \]
Moreover, it is well known that the feedback interconnection (11) of the closed-loop system and the parameter error dynamics (15) lead to the asymptotic stability of the servomechanism. This analysis will consider two cases:

(i) Closed loop identification of the unperturbed DC servomechanism, where the main objective will be to get a formula to estimate the system parameters and show the condition under which the system is exponentially stable.

(ii) Closed loop identification of the perturbed DC servomechanism where the existence of the region \( \Omega \) will be shown where the parameter estimates converge, when a perturbation signal affects the system.

### 3. Closed Loop Identification Algorithm: Nonperturbed Case

This section describes the closed loop identification approach and the way the parameter updating law is constructed. Besides, it is proved that under some assumptions the overall system is exponentially stable. Then, first the stability analysis will be presented to ensure the asymptotic stability of the closed loop system and the parameter error dynamics. Later, the system exponential stability property will be established.

#### 3.1. Stability Analysis and Parameter Convergence

The closed loop identification analysis is described similar to that presented in [14] and depicted in Figure 1. For this (unperturbed) case, it will be considered that \( v(t) \) is identically zero, leading to the following unperturbed servo model:

\[ \dot{q}(t) = -a\dot{q}(t) + bu(t). \]

The closed loop identification methodology consists of selecting a model of (11) with the following dynamics:
\[ \dot{q}_e(t) = -\hat{a}q_e(t) + b u_e(t), \]
where \( q_e(t) \) is the estimated servo position, \( \dot{q}_e(t) \) the estimated velocity, \( \hat{a}, \hat{b} \) are the estimates of \( [a, b] \), and \( u_e \) the control law for the estimated model. Then, the loop is closed around the real servomechanism and its model by using two PD controllers, where the same gains are used for both of them. Now let us define the output error \( e(t) = q(t) - q_e(t) \), and then this error and its time derivative are employed to feed an identification algorithm which estimates the system parameters and updates them in the estimated model. All this procedure is now theoretically summarized.

For closing the loop around the unperturbed system and its model, let us consider the PD controllers \( u(t) \) and \( u_e(t) \) as follows:
\[ u(t) = k_p e(t) - k_d \dot{q}(t) \quad \text{and} \quad u_e(t) = k_p e(t) - k_d \dot{q}_e(t), \]
where \( e(t) = (\dot{q}(t) - q(t)), \quad \dot{e}(t) = (\dot{q}_e(t) - q(t)). \) \( q \) is the reference signal, and \( k_p > 0, k_d > 0 \) the proportional and derivative controller gains which are used in both controllers. Then, the system (12) in closed loop with \( u(t) \) leads to the next closed-loop dynamics (for the sake of simplicity, from now on the time argument will be omitted) as
\[ \Sigma_1 : \ddot{q} = -(a + bk_d) \dot{q} + bk_p e, \]
while the system (12) in closed loop with \( u_e(t) \) leads to the following dynamics:
\[ \Sigma_2 : \ddot{q}_e = -(\hat{a} + bk_d) \dot{q}_e + bk_p e. \]

By using the Routh-Hurwitz criterion, it is easy to show that the control law \( u(t) \) stabilizes the unperturbed servomodel (11). However, even when the system (13) is stable, the same conclusion cannot be drawn for (14), because the coefficients of this estimated model (i.e., \( \hat{a}, \hat{b} \)) are updated by one identification algorithm to be described later, and then these parameters are time varying; therefore, it is necessary to analyze the stability of (14). From the definition of \( \dot{e}(t) \), it is possible to evaluate its second time derivative and employing (13) and (14), the error dynamics is established as follows:
\[ \ddot{e} + ce + bk_p e = \tilde{\Theta}^T \phi, \]
where \( c = (a + bk_d) > 0, \tilde{\Theta}(t) \) is the parameter error vector, and \( \phi(t) \) is the so-called regressor vector, where \( \tilde{\Theta} = \Theta - \theta = (\hat{a} - a, \hat{b} - b)^T, \phi(t) = (q_e, -u_e)^T \), with \( \Theta \) being the estimate of \( \theta \). In order to analyze the behavior of the signals involved in the error dynamics (15), passivity based arguments will be used [24, 25]. To this end, let \( x = (e, \dot{e})^T \) be the state vector of (15) and consider the following storage function:
\[ H_1(x) = \frac{1}{2} \mathbf{x}^T \left( \frac{b k_p}{\mu} \right) \mathbf{x} = \mathbf{x}^T M \mathbf{x}, \]
where \( \mu \in \mathbb{R}^+ \). The choice of \( H_1 \) will lead to concluding the OSP property of (15). Then, taking the time derivative of \( H_1 \) along the trajectories of (15) leads to
\[ \dot{H}_1 = \tilde{\Theta}^T \phi (\mu e + \dot{e}) - \frac{c}{2} \mu e \dot{e} - \left( \frac{c}{2} - \mu \right) \dot{e}^2 - \mu b k_p \frac{\mu e}{2} \dot{e}^2. \]

It is easy to prove that \( H_1 > 0 \) if \( \mu < \sqrt{b k_p} \). Besides, if \( \mu < \min(c/2, 2b k_p/c) \), then the time derivative of \( H_1 \) along the trajectories of (15) yields \( H_1 \leq \tilde{\Theta}^T \phi (\mu e + \dot{e}) - c \mu e \dot{e}^2 / 2; \) that is, (15) defines an OSP operator \( \tilde{\Theta}^T \phi \rightarrow (\mu e + \dot{e}) \).

Moreover, it is well known that the feedback interconnection
of passive subsystems is passive [24], thus making an intuitive

to consider the parameter error dynamics as follows: \( \Sigma_3 : \dot{\vartheta} = -\Gamma \varphi (\mu \epsilon + \dot{\epsilon}) \), with matrix \( \Gamma = \Gamma^T > 0 \). Then, by considering the

storage function \( H_2(\vartheta) = \dot{\vartheta}^T \Gamma^{-1} \dot{\vartheta} = (\epsilon + \dot{\epsilon}) (-\vartheta^T \varphi) \), so that \( \Sigma_3 \) defines the passive operator \( (\mu \epsilon + \dot{\epsilon}) \rightarrow (-\dot{\vartheta}^T \varphi) \).

Finally, let us consider the feedback interconnection of (15) with \( \Sigma_3 \) given by

\[
\begin{align*}
\Sigma \{ \frac{\varphi(t)}{\epsilon(t)} + c \varphi(t) + b_k \varphi(t) = \vartheta^T \phi(t), \\
\dot{\vartheta} = -\Gamma \varphi (\mu \epsilon + \dot{\epsilon}).
\end{align*}
\]

Then, by considering the storage function for (18) as the sum of \( H_1 \) and \( H_2 \), it is easy to prove that \( \Sigma \) is still OSP; thus, it follows that \( (\mu \epsilon + \dot{\epsilon}) \in L_2 \). Let us define the signal \( y(t) = (\mu \epsilon + \dot{\epsilon}) \) as the output for the interconnected system (18). Then, note that \( e(t) \) corresponds to the output of an exponentially stable

filter whose input belongs to the \( L_2 \) space; therefore, \( e(t) \) tends to zero as \( t \to \infty \) [26]. Therefore, it has been proved that \( q(t) \in L_\infty \), and \( e(t) \to 0 \) as \( t \to \infty \), and thus \( q(t) \to q(t) \) as \( t \to \infty \); that is, \( q(t) \in L_\infty \), and then it turns out that the time varying system (14) is stable, as desired, although it remains to prove that the parametric error converges to zero, that is, that \( \dot{\vartheta}(t) \) converges to the real parameter vector \( \vartheta \). To this end, let us consider the state-space description of (15) as

\[
\begin{align*}
\dot{x} &= Ax + Bu, \\
y &= Cx,
\end{align*}
\]

with:

\[
A = \begin{pmatrix} 0 & 1 \\ -b k_p & -c \end{pmatrix}, \quad B = \begin{pmatrix} 0 \\ 1 \end{pmatrix}, \quad C^T = \begin{pmatrix} \mu \\ 1 \end{pmatrix}, \quad U = \vartheta^T \phi.
\]

As described in [22], a necessary and sufficient condition for parameter convergence in linear systems is the PE condition of the regressor vector \( \phi(t) \). However, the results presented in [22] assume that all the signals in \( \phi(t) \) come from a linear time invariant system, which is not the case here because here the regressor \( \phi(t) \) has signals from the estimated model (14), which is a time varying system. To overcome this technical difficulty it is possible to consider the real regressor vector \( \phi_r(t) = (q, -u)^T \), which consists of signals from the real servomechanism (13). Following the same procedure as that presented in [22], it is not a difficult task to show that if \( c > \mu \), then \( \phi_r(t) \) will be PE. Now, let us consider the difference

\[
\phi_r - \phi = \begin{pmatrix} \dot{q} \\ -u \end{pmatrix} = \begin{pmatrix} \dot{q} \\ k_p \varphi + k_d \dot{\varphi} \end{pmatrix},
\]

and consider the Lyapunov function candidate \( V_1 = H_1 + H_2 \). Clearly \( V_1 > 0 \) if \( \mu < \sqrt{bk_p} \) and \( V_1 \leq -\beta \epsilon^2, \beta = (2/\alpha)(bk_p \alpha/2 - \mu^2 \epsilon^2 / 8) \), with \( \alpha = (c - \mu) > 0 \). Therefore, if \( \mu \leq 4bk_p \epsilon / (4bk_p + \epsilon^2) \), then \( e(t) \in L_2 \), and considering the fact that \( y(t) = (\mu \epsilon + \dot{\epsilon}) \in L_2 \) permits concluding that \( e(t) \in L_2 \), which makes clear that \( (\varphi_r - \varphi) \in L_2 \). Now, given a PE signal \( \omega(t) \) and a signal \( z(t) \in L_2 \), the sum \( (\omega + z) \) is still PE [22]. Thus, \( \varphi = \varphi_r - (\varphi_r - \varphi) \) is PE as desired and the convergence of \( \dot{\vartheta}(t) \) to zero can be claimed, that is, the

![Figure 1: Blocks diagram for the identification algorithm.](image)
estimated parameters converge to the real ones. Then, based on the previous analysis, the following proposition follows.

**Proposition 2.** Consider the system (13) and assume that \( \mu \leq \min\{\sqrt{bk_p}, 2bk_p/c, 4bk_p/c(4bk_p + c^2)\} \). Then, \( e, \dot{e} \) and the parameter error vector \( \tilde{\theta}(t) \) converge to zero as time tends to infinity.

From the previous result, asymptotic stability has been proved for the closed loop system and identification approach. However, in the identification framework usually it is preferable to have a more robust stability condition, that is, exponential stability to guarantee that the parameter identification scheme will be robust against disturbances which may affect the system, such as unmodeled dynamics and measurement noise. Therefore, the next analysis will establish the necessary conditions for the servomechanism to be an exponentially stable system.

### 3.2. Exponential Convergence

As mentioned above, one appealing and important property of the parameter identification schemes is the exponential stability, because it guarantees robustness of the identification algorithm in presence of external disturbances or unmodeled dynamics. Thus, in the following it will be proved which conditions must be satisfied in order to make the system to be exponentially stable. First recall the state space description given by (19). Clearly the system \((A, B, C)\) is observable and controllable [23]; that is, it is a minimal realization, if \( \mu < c/2 \). Let us consider the systems

\[
\Sigma_4 : \begin{cases}
\dot{\theta} = 0 \\
y_2 = \phi^T(t) \tilde{\theta}(t),
\end{cases} \quad \Sigma_5 : \begin{cases}
\dot{\theta} = -\Gamma \phi (\mu e + \dot{e}) \\
y_2 = \phi^T(t) \tilde{\theta}(t).
\end{cases}
\]

(22)

The last analysis proved that \( \phi(t) \) is PE which turns out to be equivalent to the UCO condition on the system \( \Sigma_4 \) and so do \( \Sigma_5 \). Then, the main result of this section can be established as follows.

**Theorem 3.** Given the system (18), assume that \( \mu \) fulfills the bound conditions of Proposition 2. Let \( w = (x, \tilde{\theta}) \) be an equilibrium point of \( \Sigma \). Then \( w \) is an exponentially stable equilibrium point.

**Proof.** Let \( w(t) = (x, \tilde{\theta})^T = (e, \dot{e}, \tilde{\theta})^T \) be the state of (18) and consider the following Lyapunov function candidate:

\[
V_2(w(t)) = H_2(\tilde{\theta}(t)) + H_3(x(t)),
\]

(23)

with \( H_2 \) as previously mentioned and \( H_3 \) defined as follows:

\[
H_3(x(t)) = \frac{1}{2} x^T M_2 x, \quad M_2 = \begin{pmatrix}
\frac{b k_p}{\mu} & \mu c \\
\mu & 1
\end{pmatrix}.
\]

Clearly, \( H_3 > 0 \) if the inequality \( \mu < (c + \sqrt{c^2 + 4bk_p})/2 \) holds. Besides, it is possible to show that

\[
\frac{1}{2} \lambda_{\min}(M_2) \|x\|^2 + \frac{1}{2} \lambda_{\min}(\Gamma) \|\tilde{\theta}\|^2 \leq V_2(w)
\]

\[
\leq \frac{1}{2} \lambda_{\max}(M_2) \|x\|^2 + \frac{1}{2} \lambda_{\max}(\Gamma) \|\tilde{\theta}\|^2.
\]

Taking the time derivative of \( V_2 \) along the trajectories of (18) yields

\[
\dot{V}_2 = -\mu b k_p 0 \begin{pmatrix} 0 & \mu c - \mu \end{pmatrix} x.
\]

(26)

Let us define the diagonal matrix \( Q = \text{diag}[\mu b k_p, c - \mu] \); then we have that \( \dot{V}_2 \leq -x^T Q x \leq 0 \), where \( Q = Q^T > 0 \) if \( \mu < c \). Now assume that there exist strictly positive constants \( \alpha_3, \delta \) such that

\[
\int_{t_0}^{t + \delta} \frac{d}{dt} V_2(w(\tau)) \bigg|_{(18)} d\tau \leq -\alpha_3 \|w(\tau)\|^2.
\]

(27)

First note from (18) and the time derivative of \( V_2 \) that

\[
\int_{t_0}^{t + \delta} \frac{d}{dt} V_2(w(\tau)) \bigg|_{(18)} \leq -\frac{\lambda_{\min}(Q)}{\mu^2 + 1} \int_{t_0}^{t + \delta} |y(\tau)|^2 d\tau,
\]

(28)

and then (27) will be valid if, for \( \alpha_3 > 0 \), the following inequality holds:

\[
\frac{\lambda_{\min}(Q)}{\mu^2 + 1} \int_{t_0}^{t + \delta} |y(\tau)|^2 d\tau \geq \alpha_3 \left( \|x(t_0)\|^2 + \|\tilde{\theta}(t_0)\|^2 \right),
\]

(29)

for all \( t_0 \geq 0 \) and \( w(t_0) \). Now consider the following system:

\[
\dot{x} = Ax + Bu, \quad \dot{\tilde{\theta}} = 0, \quad y = Cx.
\]

(30)

Let us consider the UCO property of \( \Sigma_5 \) with \( K = -\Gamma (\mu e + \dot{e}) \). It is clear that, for the UCO condition,

\[
k_{\delta} = \int_{t_0}^{t + \delta} \Gamma^T (\mu e + \dot{e})^2 \Gamma d\tau \leq \int_{t_0}^{t + \delta} \lambda_{\max}(\Gamma) (\mu e + \dot{e})^2 d\tau.
\]

(31)

Also we know that \( (\mu e + \dot{e}) \in L_2 \); thus, there exists a positive constant \( \kappa > 0 \) such that \( k_{\delta} \leq \kappa \lambda_{\max}(\Gamma) \). What’s more, the output of (19) is given by

\[
y(t) = C^T e^{A(t-t_0)} x(t_0) + \int_{t_0}^{t} C^T e^{A(t-\tau)} B \phi(\tau) d\tau \tilde{\theta}(t_0)
\]

(32)

because from (30) we note that the vector \( \tilde{\theta} \) is constant. Let us define the signals \( z_1(t) \) and \( z_2(t) \) as follows:

\[
z_1(t) = C^T e^{A(t-t_0)} x(t_0), \quad z_2(t) = \int_{t_0}^{t} C^T e^{A(t-\tau)} B \phi(\tau) d\tau \tilde{\theta}(t_0).
\]

(33)
From the stability analysis of Section 3 it was concluded that \( \{\phi(t), \dot{\phi}(t)\} \in L_\infty \) and that \( \phi(t) \) is PE. Thus, it is clear that [22] \( \phi_j(t) = \int_t^\infty C^j e^{\lambda_j t} B \dot{\phi}(r) dr \) is PE. Therefore, there exist positive constants \( \{\gamma_1, \gamma_2, \sigma\} \) such that \( \alpha_1 \|\theta(t_0)\|^2 \leq \int_{t_1}^{t_1 + \delta} z_1^2(r) dr \leq \alpha_2 \|\bar{\theta}(t_0)\|^2 \) for all \( t_1 \geq t_0 \geq 0 \) and \( \bar{\theta}(t_0) \).

Moreover, because matrix \( A \) is stable there exist positive constants \( \{\gamma_1, \gamma_2\} \) such that \( \int_{t_1}^{t_1 + \delta} z_1^2(r) dr \leq \gamma_1 \|x(t_0)\|^2 e^{-\gamma_1 \delta} \) for all \( t_0 \geq 0 \), \( x(t_0) \) and an integer \( m \geq 0 \) to be defined later. Because \( (A, C) \) is observable there exists \( \gamma_3(m\sigma > 0 \) with \( \gamma_3(m\sigma) \) increasing such that \( \int_{t_0}^{t_0 + \sigma} z_1^2(r) dr \leq \gamma_3(m\sigma) \|x(t_0)\|^2 \)

for all \( t_0 \geq 0 \), \( x(t_0) \) and \( m > 0 \). Let \( n > 0 \) be another integer to be defined and \( \delta = (m+n)\sigma \). Then

\[
\int_{t_0}^{t_0 + \delta} |y(r)|^2 dr \geq \gamma_5(m\sigma) \|x(t_0)\|^2 - \gamma_1 e^{-\gamma_1 \delta m} \|x(t_0)\|^2 \\
+ m \alpha_1 \|\bar{\theta}(t_0)\|^2 - m \alpha_2 \|\bar{\theta}(t_0)\|^2 \\
= \|x(t_0)\|^2 [\gamma_5(m\sigma) - \gamma_1 e^{-\gamma_1 \delta m}] \\
+ \|\bar{\theta}(t_0)\|^2 [m \alpha_1 - m \alpha_2].
\]

Let both \( m \) and \( n \) be large enough such that \( m \alpha_1 - m \alpha_2 \geq \alpha_1 > 0 \) and \( \gamma_5(m\sigma) - \gamma_1 e^{-\gamma_1 \delta m} \geq \gamma_5(m\sigma)/2 > 0 \); then,

\[
\int_{t_0}^{t_0 + \delta} |y(r)|^2 dr \geq \frac{\gamma_5(m\sigma)}{2} \|x(t_0)\|^2 + \alpha_2 \|\bar{\theta}(t_0)\|^2.
\]

Similarly, it is possible to conclude that

\[
\int_{t_0}^{t_0 + \delta} |y(r)|^2 dr \leq 2 \gamma_1 \|x(t_0)\|^2 e^{-\gamma_1 \delta m} + 2 (m + n) \alpha_1 \|\bar{\theta}(t_0)\|^2.
\]

Now we define \( \beta_1 = \min(\alpha_1, \gamma_1(m\sigma)/2) \) and \( \beta_2 = \max(2\gamma_1, 2(m + n)\alpha_1) \). Then, it is possible to obtain the following bounds:

\[
\beta_1 \left[ \|x(t_0)\|^2 + \|\bar{\theta}(t_0)\|^2 \right] \\
\leq \int_{t_0}^{t_0 + \delta} \|y(r)|^2 dr \leq \beta_2 \left[ \|x(t_0)\|^2 + \|\bar{\theta}(t_0)\|^2 \right],
\]

and therefore

\[
\int_{t_0}^{t_0 + \delta} \frac{d}{dr} V_2(w(r)) \bigg|_{(36)} \\
\leq -\lambda_{\min}(Q) \beta_1 \left[ \|x(t_0)\|^2 + \|\bar{\theta}(t_0)\|^2 \right] \\
\leq -\alpha_3 \|w_0\|. 
\]

where \( \alpha_1 = \min(\lambda_{\min}(M_2), \lambda_{\max}(\Gamma)/2), \alpha_2 = \max(\lambda_{\max}(M_2), \lambda_{\min}(\Gamma)/2), \alpha_3 = \lambda_{\min}(Q) \min(\alpha_1, \gamma_3(m\sigma)/2)/(\mu^2 + 1) \). Then we conclude that the system \((18)\) is exponentially stable.

The last result established the exponential stability of \((18)\) for the unperturbed case. However, in practice there are several disturbance sources (e.g., unmodeled dynamics, noise from the environment or from the measuring devices, etc.) which may affect the system performance of both the system and the identification algorithm. Therefore, the next analysis shows the extension of the last analysis to those scenarios.

### 4. Closed-Loop Identification Algorithm: Perturbed Case

Till now exponential stability of the equilibrium of \((18)\) has been established. Now, it will be considered the perturbed system \((10)\) in closed loop with the PD controller \(u(t)\) and it will be proved that this closed loop system is \(L_{\infty}\) stable in the sense of Theorem 1. Let us consider the system \((10)\) in closed loop with \(u(t)\), the system \(\Sigma_2\), and the output error \(e(t)\) defined as before. Then, it is possible to obtain the following error dynamics:

\[
\dot{e}(t) = -ce(t) - bk_\gamma e(t) + \theta^T \phi(t) + \nu(t).
\]

For the system \((39)\) it is important to know if it is still stable in the presence of the perturbation signal \(\nu(t)\). If it is the case, then the system will be robust even in the presence of perturbations, which is desirable in the identification context because reliable parameter estimates can be obtained even in the perturbed case. The next result obtained from [22] allows concluding that the perturbed system \((39)\) is \(L_{\infty}\) stable.

**Theorem 4.** Consider the perturbed system \((39)\) and the unperturbed system \((18)\). If the equilibrium \(w_0\) of \((18)\) is exponentially stable, then one has the following.

1. The perturbed system \((39)\) is small signal \(L_{\infty}\)-stable; that is, there exists \(\gamma_{\infty}\) such that \(\|w(t)\| \leq \gamma_{\infty} \beta < h\), where \(w(t)\) is the solution of \((39)\) starting at \(w_0\).

2. There exists \(m \geq 1\), such that \(\|w_0\| < h/m\) implies that \(w(t)\) converges to a ball \(B_{\beta}\) of radius \(\beta = \gamma_{\infty} \beta < h\); that is, for all \(\varepsilon > 0\), there exists \(T \geq 0\) such that \(\|w(t)\| \leq \delta(1+\varepsilon)\) for all \(t \geq T\), along the solutions of \((39)\) starting at \(w_0\). Also for all \(t \geq 0\), \(\|w(t)\| < h\).

**Proof.** Consider again the Lyapunov function \(V_2(w(t))\). Assuming that inequalities for \(\mu\) given in Proposition 2, it is possible to obtain \(V_2 \leq -\lambda_{\min}(Q)\|x\|^2 + \beta \sqrt{\mu^2 + 1}\|x\|\).

Let us define the constants \(\alpha_5 = \lambda_{\min}(Q),\alpha_4 = \sqrt{\mu^2 + 1},\gamma_{\infty} = \alpha_3/\alpha_5,\gamma_{\infty} = \alpha_4/\alpha_5,\delta = \gamma_{\infty} \beta,\) and \(m = \sqrt{\alpha_4/\alpha_5} \geq 1\). Then, the time derivative of \(V_2(w(t))\) along the trajectories of \((39)\) yields \(V_2 \leq -\alpha_3\|x\|\||x| - \delta/m\|\) and two cases may be considered.

1. First it will be proved that \(\|w(t)\| \leq \gamma_{\infty} \beta < h\). To this end consider the case where \(\|x_0\| \leq \delta/m\). Note
that $\delta/m \leq \delta$ because of $m \geq 1$, which implies that $w(t) \in \Omega_\delta$ for all $t \geq 0$. Suppose that it is not true, and then, by continuity of the solutions there exists $T_0$ and $T_1$, with $T_1 > T_0 \geq 0$ such that $\|x(T_0)\| = \delta/m$, $\|x(T_1)\| > \delta$ and for all $t \in [T_0, T_1]$: $\|w(t)\| \geq \delta/m$, and then, from the time derivative of $V_2$ it is clear that in $[T_0, T_1]$: $V_2 \leq 0$, but in this case $V_2(T_0, x(T_0)) \leq \alpha_2(\delta/m)^2 = \alpha_2\delta^2$ and $V_2(T_1, x(T_1)) > \alpha_2\delta^2$, which is a contradiction; therefore, for all $w(t)$ with initial condition $w_0$, a solution for (39) remains on $\Omega_\delta$.

(2) Assume that $\|w_0\| > \delta/m$ and that for all $\epsilon > 0$ there exists $T_0 \geq 0$ such that $\|w(T)\| < \delta(1+\epsilon)/m$ and suppose that it is not true; then, for some $\epsilon > 0$ and for all $t \geq 0$: $\|w(t)\| > \delta(1+\epsilon)/m$ and from the time derivative of $V_2$ given previously it is possible to obtain $V_2 \leq -\alpha_2(\delta/m)^2\epsilon(1+\epsilon)$, which is a strictly negative constant. However, this contradicts with the fact that $V_2(0, x_0) \leq \alpha_2\|x_0\|^2 < \alpha_2\epsilon^2/m^2$, $V_2(t, x(t)) \geq 0$ for all $t \geq 0$, because the inequality must be strict. On the other hand, let us assume that for all $t \geq T$ the following inequality holds: $\|x(t)\| < \delta(1+\epsilon)$ and it is possible to probe this affirmation in the same way that the first step of this proof. Thus, we conclude that $w(t)$ converges to $\Omega_\delta$, as desired, and the proof is completed.

5. Analysis of the Results

The previous analysis showed that even in the presence of a bounded perturbation signal the parameter estimates remain in a region $\Omega_\delta = \gamma_\text{co} \beta$. Now it is important to analyze the behavior of this region and to see how the controller gains influence the way this region behaves. To this end, recall from Theorem 4 that the state of (39) is bounded by

$$\Omega_\delta = \gamma_\text{co} \beta = \sqrt{\frac{(\mu^2 + 1) \beta^2 \max(\lambda_{\max}(M_2), \lambda_{\max}(\Gamma))}{(\min(\lambda_{\min}(Q)))^2 \min(\lambda_{\min}(M_2), \lambda_{\min}(\Gamma))}}. \tag{40}$$

Besides, it is easy to obtain the eigenvalues $\lambda_i$ of $M_2$ as $\lambda_i = (bk_p + \mu c + 1 \pm \sqrt{(bk_p + \mu c - 1)^2 + 4\mu^2})/2$. Thus, the minimal ($\lambda_{\min}$) and maximum ($\lambda_{\max}$) eigenvalues for $M_2$ are given by

$$\lambda_{\min}(M_2) = \frac{bk_p + \mu c + 1 - \sqrt{(bk_p + \mu c - 1)^2 + 4\mu^2}}{2}, \tag{41}$$

$$\lambda_{\max}(M_2) = \frac{bk_p + \mu c + 1 + \sqrt{(bk_p + \mu c - 1)^2 + 4\mu^2}}{2}.$$  

Besides, for the diagonal matrix $Q$, note that $\lambda_{\min}(Q) = \min\{\mu bk_p + c - \mu\}$, $\lambda_{\max}(Q) = \max\{\mu bk_p + c - \mu\}$. Then, note that the region $\Omega_\delta$ depends on several parameters, among which are the controller gains $k_p$ and $k_d$. In order to see the effect of the controller gains, let us consider the minimal and maximum eigenvalues of $M_2$. From (40), it is possible to note that the region $\Omega_\delta$ can be reduced by minimizing the value of $\lambda_{\max}(M_2)$ and maximizing that of $\lambda_{\min}(M_2)$; that is, the value of $\sqrt{(bk_p + \mu c - 1)^2 + 4\mu^2}$ must be the minimum possible. Then, let us consider the function $f_m(\mu, k_p, k_d) = (bk_p + \mu c - 1)^2 + 4\mu^2$ and its first and second partial derivatives with respect to $\mu$, $k_p$, and $k_d$ as follows:

$$\frac{\partial f_m}{\partial \mu} = 2c \left(bk_p + \mu c - 1\right), \quad \frac{\partial^2 f_m}{\partial \mu^2} = 2c^2,$$

$$\frac{\partial f_m}{\partial k_p} = 2b \left(bk_p + \mu c - 1\right), \quad \frac{\partial^2 f_m}{\partial k_p^2} = 2b^2,$$

$$\frac{\partial f_m}{\partial k_d} = 2\mu b \left(bk_p + \mu c - 1\right), \quad \frac{\partial^2 f_m}{\partial k_d^2} = 2\mu^2 c.$$  \tag{42}

If we set the first partial derivatives to zero, we obtain the equilibrium points $(\mu^*, k_p^*, k_d^*)$ with the following expressions:

$$k_p^* = \frac{1 - \mu c}{b}, \quad k_d^* = \frac{1 - \left(bk_p + \mu a\right)}{\mu b}, \quad \mu^* = \frac{c \left(1 - bk_p\right)}{c^2 + 4}. \tag{43}$$

Now, let us analyze the qualitative behavior of the region $\Omega_\delta$ for different values of $\lambda_{\min}(Q)$, $\lambda_{\min}(\Gamma)$, $\lambda_{\max}(Q)$, $\lambda_{\max}(\Gamma)$, $k_p$, $k_d$, and $\mu$. Figure 2 depicts the behavior of region $\Omega_\delta$ for different values of $k_p$ and $k_d$ (the controller gains) and Figure 3 shows also the $\Omega_\delta$ behavior for different values of $\lambda_{\min}(Q)$ and $\lambda_{\max}(Q)$ (the matrix related with the identification algorithm). From this set of graphics and (40), note the following.

(i) For a given constant value of $k_d$ and $\mu$, if $k_p$ is big, the value of $k_p^*$ is reduced and the region $\Omega_\delta$ is also reduced. For a given constant value of $k_p$, if $k_p$ is big, the values of $k_d^*$ and $\mu^*$ are reduced, which turns out to reduce again the size of the region $\Omega_\delta$.

(ii) The region $\Omega_\delta$ can be made arbitrarily small if the values of $\lambda_{\min}(Q)$ and $\min(\lambda_{\min}(M_2), \lambda_{\min}(\Gamma))$ are as large as possible and the value for $\lambda_{\min}(Q)$ can be increased if the controller gains $k_d$ and $k_p$ have large values, which is the case if a high gain PD controller is used. Then, the size of $\Omega_\delta$ may be reduced and therefore the quality of the parameter estimates may be improved by means of the controller gains.

(iii) By increasing the value of $k_p$ and $k_d$, the value of $\lambda_{\min}(M_2)$ is increased, which may reduce the size of $\Omega_\delta$ and by increasing the values of the gain matrix $\Gamma$, the value of $\lambda_{\min}(\Gamma)$ is also increased, reducing then the size of $\Omega_\delta$.

(iv) As it can be seen from Figure 4, for the controller gains, the effect of the gain $k_p$ is more important for reducing the size of region $\Omega_\delta$ than that of gain $k_d$, because large values of $k_d$ do not influence significantly in the reduction of the region $\Omega_\delta$. What's more, the effect of gain $k_d$ is almost imperceptible if the gain $k_p$ is large enough.
Finally, as expected, if the values of the maximum or minimum eigenvalues for the gain matrix $\Gamma$ dominate, the size of $\Omega_\delta$ will also be reduced.

From the last analysis, it is possible to conclude that, for robustness of the identification algorithm, it is important to pay attention not only to the setup of the gain matrix $\Gamma$ and $\mu$ from the identification algorithm, but also to the value of the controller gains $k_p$ and $k_d$. Then, the region $\Omega_\delta$ is effectively reduced if a high gain $k_p$ is employed, and also if large eigenvalues are assigned to matrix $\Gamma$.

Another subject to be considered is the controller structure, because it is possible to note that not all the gains have the same effect of reducing region $\Omega_\delta$. Therefore, when the parameter identification algorithm is designed, it is important to note that the structure of the controller should be an important issue that has been underestimated and that will be important in real applications where noisy measurements or unmodeled dynamics may be affecting the system.

6. Conclusion

This paper analyzes a method for on-line closed loop identification of a linear DC servomechanism with a bounded perturbation signal and a PD controller. Theoretical results show that, without perturbation signals, the system is exponentially stable and the parameter error converges to zero, but when a perturbation signal is present, the parameter estimates converge to a region $\Omega_\delta$ and the overall system is $L_\infty$ stable; that is, the system is robust in face of perturbation signals. Besides, by increasing the controller and adaptation gains the region $\Omega_\delta$ can be arbitrarily reduced, which means that the accuracy of the parameter estimates can be increased, which gives some insight into the importance of the controller.
structure in the identification process. Future work will be devoted to design more complicated controllers and verify the controller structure needed to obtain a better estimate of the system parameters, that is, a controller which reduces $\Omega_\delta$ as much as possible and ensures the overall exponential stability.
