Networked control system is a research area where the theory is behind practice. Closing the feedback loop through shared network induces time delay and some of the data could be lost. So the network induced time delay and data loss are inevitable in networked control Systems. The time delay may degrade the performance of control systems or even worse lead to system instability. Once the structure of a networked control system is confirmed, it is essential to identify the maximum time delay allowed for maintaining the system stability which, in turn, is also associated with the process of controller design. Some studies reported methods for estimating the maximum time delay allowed for maintaining system stability; however, most of the reported methods are normally overcomplicated for practical applications. A method based on the finite difference approximation is proposed in this paper for estimating the maximum time delay tolerance, which has a simple structure and is easy to apply.

1. Introduction

The key feature of networked control systems (NCSs) is that the information is exchanged through a network among control system components. So the network induced time delay is inevitable in NCSs. The time delay, either constant (up to jitter) or random, may degrade the performance of control systems and even destabilize the systems. NCSs can be defined as a control system where the control loop is closed through a real-time communication network [1]. The term networked control systems first appeared in Walsh’s article in 1999 [2]. A typical organization of an NCS is shown in Figure 1. The reference input, plant output, and control input are exchanged through a real-time communication network. The main advantages of NCSs are modularity, simplified wiring, low cost, reduced weight, decentralization of control, integrated diagnosis, simple installation, quick and easy maintenance [3], and flexible expandability (easy to add/remove sensors, actuators, or controllers with low cost). NCSs are able to easily fuse global information to make intelligent decisions over large physical spaces which is important for many engineering systems such as the power system.

As the control loop is closed through a communication network the time delay and data dropout are unavoidable. Therefore networked control system can be regarded as a special case time delay system and many authors applied the time delay theorems to study NCSs [4]. Time delay, no doubt, increases complexity in analysis and design of NCSs. Conventional control theories built on a number of standing assumptions including synchronized control and nondelayed sensing and actuation must be reevaluated before they can be applied for NCSs [5].

The main goal of the most recent work is to reduce the conservativeness of the maximum time delay by using Lyapunov-Krasovskii functional with improved algorithms for solving the linear matrix inequalities (LMIs) set but with the expense of increasing complexity and computation time. Analytical and graphical methods have been studied in the literature (see, e.g., [6]). The stability criteria for NCSs based on Lyapunov-Krasovskii functional approach have been reported in [7–9]. In [7], a Lyapunov-Krasovskii function is used to derive a set of LMIs and the stability problem is generalized to a feasibility problem for the LMIs set. In many of the previously reported works, the controller is
designered in the absence of the time delay. In [10], an improved Lyapunov-Krasovskii function is used with triple integral terms. The LMI methods require the closed-loop system to be Hurwitz [8, 11, 12]. In [13], a modified cone complementary linearization algorithm based on the Lyapunov-Krasovskii approach is implemented. And the method reported in [14] is claimed to be less conservative and the computational complexity is reduced.

The authors in [15] derived an LMI-based method in the frequency domain, and then the LMI is transformed onto an equivalent nonfrequency domain LMI by applying Kalman-Yakubovich-Popov lemma. It has been reported in [16] that the ordinary Lyapunov stability analysis is linked by a suggested variable to state vectors through convolution and the stability analysis is simplified to only require solving a nonlinear algebraic matrix equation.

In [11], the hybrid system technique is used to derive a stability region. An upper bound is derived for time delay in an inequality form and the results are rather conservative. The hybrid system stability analysis technique has also been used in [17]. A simple analytical relation is derived between the sampling period, the time delay, and the controller gains. The same approach is used in [18] with more conservative stability region results. The model-based approach for deriving necessary and sufficient conditions for stability is presented in [19]. The stability criteria are derived in terms of the update time and the parameters of the model. The model-based approach is then extended to multiunits NCS in [20]. The optimal stochastic control was studied in [21] with a discrete-time system model where the random time delays are modeled using Markov chains and the controller uses the knowledge of the past state time delays by time stamping.

Most of the previously developed approaches require excessive load of computations, and also, for higher order systems, the load of computations will increase dramatically. In practice, engineers may find it difficult to apply those available methods in control system design because of the complexity of the methods and lack of guideline in linking between the design parameters and the system performance. Almost all the design procedures highly depend on the postdesign simulation to determine the design parameters. So there is a demand for a simple design approach with clear guidance for practical applications. In this paper, a new stability analysis and control design method is proposed, in which the design approach is simple and a clear design procedure is given.

The paper starts from the mathematical model of NCS and then the proposed method for estimating the maximum allowable delay bound is briefly described. A few examples are illustrated and the results are compared with those previously published in the literature. The cart and inverted pendulum problem is used to study the effect of the parameters on the maximum allowable delay bound.

2. Mathematical Analysis

Although the issues involved with time delays in control systems have been studied for a long time, it is difficult to find a method simple enough to be accepted by control system design engineers. It is found that the most previously reported methods rely on LMI techniques and they are generally too complicated for practical engineers to use and also involve heavy load of numerical calculations and computing time. The paper proposes a new method which has a simple structure and is used for estimating the maximum time delay allowed while the system stability can still be maintained. In most control systems the sampling time is preferred to be small [22]. The maximum allowable delay bound (MADB) can be defined as the maximum sampling period that guarantees the stability even with poor system performance. A continuous time-invariant linear system is shown in Figure 2 and given by

\[ \dot{x}(t) = Ax(t) + Bu(t), \]
\[ y(t) = Cx(t) + Du(t), \]

where \( x(t) \in \mathbb{R}^n \) is the system state vector, \( u(t) \in \mathbb{R}^m \) is the control input, \( y(t) \in \mathbb{R}^p \) is the system output, and \( A \in \mathbb{R}^{n \times n}, B \in \mathbb{R}^{n \times m}, C \in \mathbb{R}^{p \times n}, \) and \( D \in \mathbb{R}^{p \times m} \) are constant matrices with appropriate sizes.

Suppose that the control signals are connected to the control plant through a kind of network, so the time delay is inevitable to be involved in the feedback loop. The state feedback is therefore can be written as

\[ u(t) = Kx(t - \tau_{sc} - \tau_c - \tau_{ca}), \]

where \( \tau_{sc} \) is the time delay between the sensor and the controller, \( \tau_c \) is the time delay in the controller, and \( \tau_{ca} \) is the time delay from the controller to the actuator. \( K \) represents the feedback control gains with appropriate size. From (2) the networked control system can be modeled where the time delay is lumped between the sensor and the controller as shown in Figure 3.

The time delay may be constant, variable, or even random. In NCSs, the time delay is composed of the time delay from sensors to controllers, time delay in the controller, and controllers to actuators time delay which is given by

\[ \tau = \tau_{sc} + \tau_c + \tau_{ca}. \]

For a general formulation the packet dropouts can be incorporated in (3) as follows:

\[ \tau = \tau_{sc} + \tau_c + \tau_{ca} + dh, \]
where \( d \) is the number of dropouts and \( h \) the sampling period. And by (4) the data dropouts can be considered as a special case of time delay [23, 24]. It is supposed that the following hypotheses hold.

**Hypothesis 1 (H.1).** (i) The sensors are clock driven. (ii) The controllers and the actuators are event driven. (iii) The data are transmitted as a single packet. (iv) The old packets are discarded. (v) All the states are available for measurements and hence for transmission.

**Hypothesis 2 (H.2).** The time delay \( \tau \) is small to be less than one unit of its measurement.

**Definition 1 (D.1).** For a function \( f(t) \), the \( n \)th order remainder for its Taylor’s series expansion is defined by

\[
R_n \left( f(t), \tau \right) = \sum_{n=0}^{\infty} \frac{f^{(n)}(\tau)}{n!} t^n.
\]

Applying the state feedback proposed in (2) to the system (1), we have

\[
\dot{x}(t) = Ax(t) + BKx(t - \tau).
\]

From (6), the following can be derived:

\[
\dot{x}(t) = (A + BK)x(t) + BK[x(t - \tau) - x(t)].
\]  

**Theorem 2.** Suppose that (H.1) and (H.2) hold. For system (1) with the feedback control of (2), the closed-loop system is globally asymptotically stable if \( \lambda_j(\Psi) \in \mathbb{C}^+ \), for \( i = 1, 2, \ldots, n \) and all the state variables’ 2nd order reminders are small enough for the given value of \( \tau \), where \( \Psi \) is given by

\[
\Psi = \left[ (I + \tau BK)^{-1} (A + BK) \right].
\]

**Proof.** For system (1), suppose that the state feedback has been designed to ensure \( \lambda(A + BK) \in \mathbb{C}^+ \). Therefore, for a chosen positive definite matrix \( P = P^T \), it will find a positive definite matrix \( Q = Q^T \) to have

\[
P(A + BK) + (A + BK)^T P = -Q.
\]
Choose a Lyapunov functional candidate as
\[ V(x) = x^T P x > 0 \quad \forall x \neq 0. \] (18)
The objective for the next step is to find the range of \( \tau \) that will ensure \( V(x) < 0 \quad \forall x \neq 0 \) [25–27]. Taking the derivative of (18),
\[ \dot{V}(x) = x^T P \dot{x} + x^T \dot{x} P x \]
\[ = x^T \left[ (A + BK)^T P (I + \tau BK)^{-T} P \right. \]
\[ + P (I + \tau BK)^{-1} P^{-1} P (A + BK) \big] x \]
\[ - x^T \left[ P (A + BK) + (A + BK)^T P \right] x \]
\[ + x^T \left[ P (A + BK) + (A + BK)^T P \right] x \]
\[ = x^T \left[ (A + BK)^T P (I + \tau BK)^{-T} P \right. \]
\[ - (A + BK)^T P + P (I + \tau BK)^{-1} P^{-1} P (A + BK) \]
\[ - P (A + BK) \right] x - x^T Q x. \] (19)
Rearranging the terms in the above equation, then
\[ V(x) \approx x^T \left[ (A + BK)^T P \left[ (I + \tau BK)^{-1} P - I \right] \right. \]
\[ + \left[ P (I + \tau BK)^{-1} P^{-1} - I \right] P (A + BK) \big] x \]
\[ - x^T Q x. \] (20)
If \( P(I + \tau BK)^{-1} P^{-1} - I = I \) then (20) will become
\[ x^T \left[ P (A + BK) + (A + BK)^T P \right] x - x^T Q x = 0. \] (21)
Move the last term to the right hand side; the following will be derived:
\[ x^T \left[ P (A + BK) + (A + BK)^T P \right] x = x^T Q x. \] (22)
So \( \|P(A + BK) + (A + BK)^T P\| \cdot \|x\|^2 = \|Q\| \cdot \|x\|^2 \).
Assuming that we can find a positive number to make the following hold:
\[ \|P(A + BK) + (A + BK)^T P\| = 2 \gamma \|P \| = \|Q\| \] (23)
then \( \gamma \) can be considered as the norm of \( P^{-1}(I + BK)^{-1} P - I \).
Therefore, we have
\[ x^T \left[ (A + BK)^T P \left[ P^{-1}(I + \tau BK)^{-T} P - I \right] \right. \]
\[ + \left[ P (I + \tau BK)^{-1} P^{-1} - I \right] P (A + BK) \big] x \]
\[ \leq 2 \left\| \left[ P^{-1}(I + \tau BK)^{-T} P - I \right] P (A + BK) \right\| \cdot \|x\|^2. \] (24)
Choose
\[ \left\| P^{-1}(I + \tau BK)^{-1} P - I \right\| \leq 1. \] (25)
Use Neumann series formula for the inverse of the sum of two matrices:
\[ (I + \tau BK)^{-1} \]
\[ = I - \tau BK + \tau^2 (BK)^2 - \tau^3 (BK)^3 + \cdots. \] (26)
For small time delays \( \tau \ll 1 \) (26) can be given as
\[ (I + \tau BK)^{-1} \approx I - \tau BK. \] (27)
Applying (27) into (25) then we have
\[ \left\| P^{-1}(I + \tau BK)^{-1} P - I \right\| \]
\[ = \left\| P^{-1}(I - \tau BK) P - I \right\| = \|\tau BK\| < 1. \] (28)
And finally we get
\[ \tau < \frac{1}{\|BK\|}. \] (29)
That is, for any \( \tau < 1/\|BK\| \), \( \dot{V}(x) < 0 \), the system will be globally asymptotically stable.

Theorem 2 and Corollary 3 give us a simple tool in estimating the maximum allowable time delay for NCSs. Further analysis in the frequency domain is described below. Taking Laplace transform of (12), we have
\[ sX(s) = (A + BK) X(s) - \tau sBKX(s), \]
\[ [sI - (A + BK) + \tau sBK] X(s) = 0. \] (30)
The characteristics equation is defined as
\[ [sI - (A + BK) + \tau sBK] = 0. \] (31)
For a stable system the roots of the characteristics equation (31) must lie in the left hand side of the \( s \)-plane. From the characteristics equation, it is clear that the term \( \tau sBK \) influences the system performance and the stability as the term of \( \tau sBK \) may push the closed-loop system poles toward the right hand side of the \( s \)-plane.
As we have seen the system characteristic is determined by the term \( \tau BKx(t) \) in a certain level. This term can be regarded as a differentiator in the feedback loop, so it will introduce extra zeros to the closed-loop system and the time delay can be considered to have resulted in a variable gain to the feedback path. For more accurate estimation the second or third-order difference approximation can be used as follows:
\[ \begin{bmatrix} sI - (A + BK) + \tau sBK - \frac{\tau^2 s^2}{2} BK \end{bmatrix} = 0, \]
\[ \begin{bmatrix} sI - (A + BK) + \tau sBK - \frac{\tau^2 s^2}{2} BK + \frac{\tau^3 s^3}{6} BK \end{bmatrix} = 0. \] (32)
In the following a simple corollary for estimating the MADB in single-input-single-output NCS will be derived.
Corollary 4. Suppose that (H.1) and (H.2) hold. The system (2) with the controller (3) is asymptotically stable if
\[ \tau < \frac{1}{|\lambda_{\min}(BK)|}. \]  

Proof. The main assumption is that the eigenvalues of the compensator, BK, are all negative, \( s_1 < 0, \ldots, s_n < 0 \), and are given by
\[ BK - sI_{n \times n} = \begin{bmatrix} a_{11} - s & a_{12} & \cdots & a_{1n} \\ a_{21} & a_{22} - s & \cdots & a_{2n} \\ \vdots & \vdots & \ddots & \vdots \\ a_{n1} & a_{n2} & \cdots & a_{nn} - s \end{bmatrix}. \]  

The characteristic equation is the determinant of (34). Assume that the eigenvalues are given by
\[ s_1 = \alpha_1, \ldots, s_n = \alpha_n, \]
\[ \alpha_1 < 0, \ldots, \alpha_n < 0. \]  

Preliminary 1 (inverse eigenvalues theorem [28]). Given a matrix \( X \) that is nonsingular, with eigenvalues \( \lambda_1, \ldots, \lambda_n > 0 \), \( |\lambda_1|, \ldots, |\lambda_n| \) are eigenvalues of \( X \) if and only if \( \lambda_1^{-1}, \ldots, \lambda_n^{-1} \) are eigenvalues of \( X^{-1} \).

The eigenvalues of \( (I_{n \times n} + \tau BK) \) are given by
\[ \Delta(\tau BK + I_{n \times n} - \lambda I_{n \times n}) = \text{det}\left( \begin{bmatrix} \tau a_{11} + 1 - \lambda & \tau a_{12} & \cdots & \tau a_{1n} \\ \tau a_{21} & \tau a_{22} + 1 - \lambda & \cdots & \tau a_{2n} \\ \vdots & \vdots & \ddots & \vdots \\ \tau a_{n1} & \tau a_{n2} & \cdots & \tau a_{nn} + 1 - \lambda \end{bmatrix} \right), \]

\[ \Delta(\tau BK + I_{n \times n} - \lambda I_{n \times n}) = \tau^n \text{det}\left( \begin{bmatrix} a_{11} + \frac{1}{\tau} & a_{12} & \cdots & a_{1n} \\ a_{21} & a_{22} + \frac{1}{\tau} & \cdots & a_{2n} \\ \vdots & \vdots & \ddots & \vdots \\ a_{n1} & a_{n2} & \cdots & a_{nn} + \frac{1}{\tau} \end{bmatrix} \right). \]

Replacing \((1 - \lambda)/\tau\) by \(-s\) in (37) we get
\[ = \tau^n \text{det}\left( \begin{bmatrix} a_{11} - s & a_{12} & \cdots & a_{1n} \\ a_{21} & a_{22} - s & \cdots & a_{2n} \\ \vdots & \vdots & \ddots & \vdots \\ a_{n1} & a_{n2} & \cdots & a_{nn} - s \end{bmatrix} \right) = 0. \]  

Solving (38) the eigenvalues are given as
\[ \frac{(\lambda_1 - 1)}{\tau} = \alpha_1, \ldots, \frac{(\lambda_n - 1)}{\tau} = \alpha_n, \]
\[ \alpha_1 < 0, \ldots, \alpha_n < 0, \]  

If \( \tau < \frac{1}{|\alpha_{\min}|} \) then all the eigenvalues are positive and the system is asymptotically stable, and if \( \tau > \frac{1}{|\alpha_{\min}|} \) at least one of the eigenvalues will be negative then.

If \( \tau < \frac{1}{|\lambda_{\max}(BK)|} \) and (H.1) and (H.2) hold then the system is asymptotically stable.

Corollary 5. Suppose that (H.1) and (H.2) hold. For system (1) with the control law (2), the closed-loop system is globally asymptotically stable if
\[ \tau < \frac{1}{\max(\text{abs}(BK))} \]  

(39)

From Preliminary 1, the signs of the eigenvalues of \((I_{n \times n} + \tau BK)^{-1}\) and \((I_{n \times n} + \tau BK)\) are the same. For a single-input-single-output control system the matrix \( BK \) can be written as
\[ BK = \begin{bmatrix} b_1 k_1 & b_2 k_1 & \cdots & b_k k_1 \\ \vdots & \vdots & \ddots & \vdots \\ b_n k_1 & b_n k_2 & \cdots & b_n k_n \end{bmatrix}. \]  

(40)

The interesting property of \( BK \) is that it is singular. The eigenvalues of \( BK \) are given by
\[ BK - \lambda I_{n \times n} = \begin{bmatrix} b_1 k_1 - \lambda & b_2 k_1 & \cdots & b_k k_1 \\ \vdots & \vdots & \ddots & \vdots \\ b_n k_1 & b_n k_2 - \lambda & \cdots & b_n k_n \end{bmatrix}. \]  

(41)

The characteristics equation of \( BK \) is the determinant of (42) and is given by
\[ \lambda^n - \text{Tr}(BK) \lambda^{n-1} + \frac{1}{2} \text{Tr}(BK^2) - \text{Tr}(BK)^2 \]
\[ + \cdots + \frac{1}{2} \text{Tr}(BK^2) - \text{Tr}(BK)^2 \]
\[ = 0. \]  

(42)

Because \( BK \) is singular \( \det(BK) = 0 \) and hence
\[ \det(BK) = \frac{1}{2} \text{Tr}(BK^2) - \text{Tr}(BK)^2 = 0, \]
\[ \text{Tr}(BK^2) = \text{Tr}(BK)^2. \]  

(43)

(44)
Substituting (44) into (43), then (43) becomes
\[
\lambda^2 - \Tr(BK) \lambda \rightarrow \lambda (\lambda - \Tr(BK))
\]
(45)
\[
(-1)^n \lambda^n - \Tr(BK) \lambda^{n-1} \rightarrow (-1)^n \lambda^{n-1} (\lambda - \Tr(BK)).
\]
Finally the eigenvalues of BK are
\[
\lambda_1, \ldots, \lambda_{n-1} = 0 \quad \lambda_n = \Tr(BK) < 0. \quad (46)
\]
Equation (46) shows that the minimum eigenvalue of BK equals \(\Tr(BK)\). If the eigenvalues of \(I_{\text{non}} + \tau BK\) are \(s_1, \ldots, s_n\), then the eigenvalues of \((I_{\text{non}} + \tau BK)^{-1}\) are \(1/s_1, \ldots, 1/s_n\). The eigenvalues of \((I_{\text{non}} + \tau BK)\) are given by
\[
\tau \cdot BK + I_{\text{non}} - sI_{\text{non}}
\]
\[
\begin{bmatrix}
\tau b_{k_1} + 1 - s & \tau b_{k_2} & \cdots & \tau b_{k_n} \\
\tau b_{k_1} & \tau b_{k_2} + 1 - s & \cdots & \tau b_{k_n} \\
\vdots & \vdots & \ddots & \vdots \\
\tau b_{k_1} & \tau b_{k_2} & \cdots & \tau b_{k_n} + 1 - s
\end{bmatrix}
\]
(47)
By solving (47) it can be found that
\[
s_1, \ldots, s_{n-1} = 1,
\]
\[
s_n = 1 + \tau \cdot \Tr(BK) = 1 + \tau \cdot \lambda_{\text{max}}(BK)
\]
if \(\tau < 1/|\Tr(BK)| \rightarrow s_n > 0 \rightarrow s_1, \ldots, s_n > 0.
\]
For single-input-single-output NCS we have
\[
\abs(BK) = \Tr(BK) \quad \text{then}
\]
(49)
if \(\tau < 1/|BK| \) and both (H.1) and (H.2) hold then the system is asymptotically stable.

This inequality can be used as a simple and fast tool for estimating the MADB in NCS and involves only single calculation.

3. Stability Analysis Case Studies

In general, two approaches are applied to controller design for NCSs. The first approach is to design a controller without considering time delay and then to design a communication protocol that minimizes the effects caused by time delays. The second approach is to design the controller while taking the time delay and data dropouts into account [11, 29]. The proposed method in this paper is used to estimate the MADB for predesigned control system. In this section, a number of examples are studied to demonstrate the proposed method and compare its results with the previously published cases in the literature. In particular, the results derived using the method proposed in this paper have been compared with the results using the LMI method given in [7] and with the fourth-order Pade approximation. The fourth-order Pade approximation [6] is used for the delay term in the s-domain and is defined as
\[
e^{-\tau s} \approx P_d(s) = \frac{N_d(s)}{D_d(s)} = \frac{\left(\sum_{k=0}^{n} (-1)^k \tau^k s^k\right)}{\left(\sum_{k=0}^{n} \tau^k s^k\right)}, \quad (50)
\]
The coefficients are given by
\[
c_k = \frac{(2n-k)!n!}{(2n)!k!(n-k)!} k = 0, 1, \ldots, n \quad (n = 4). \quad (51)
\]
With the fourth-order Pade approximation, the truncation error in the time delay calculation is less than 0.0001. The LMI-based method which has been used for the comparisons is based on using Lyapunov-Krasovskii functional and can be summarized as follows.

Corollary 6 (see [7]). For a given scalar \(\tau\) and a matrix K, if there exist matrices \(P > 0\), \(T > 0\), \(N_i\), and \(M_i (i = 1, 2, 3)\) of appropriate dimension such that
\[
\begin{bmatrix}
M_1 + M_1^T - N_1 A - A^T N_1^T & M_1^T - M_1 - A^T N_1^T - N_1 BK & M_1^T - A^T N_1^T + N_1 + P & \tau M_1 \\
* & -M_2 - M_2^T - N_2 BK - (BK)^T N_2^T & -M_2^T + N_2 - (BK)^T N_2^T & \tau M_2 \\
* & * & N_3 + N_3^T + \tau T & \tau M_3 \\
* & * & * & -\tau T
\end{bmatrix}< 0, \quad (52)
\]
then the system (1)-(2) is exponentially asymptotically stable.

Example 7. The system in this example is the most widely used example in the literature and is described by the following equation:
\[
\dot{x}(t) = \begin{bmatrix} 0 & 1 \\ 0 & -0.1 \end{bmatrix} x(t) + \begin{bmatrix} 0 \\ 0.1 \end{bmatrix} u(t). \quad (53)
\]
In previous reports [1, 7], the feedback control is chosen to be
\[
u(t) = [-3.75 \quad -11.5] x(t). \quad (54)
\]
From Corollary 3, \(1/\|BK\| = 0.8695\), so the MADB is estimated to be 0.8695 s. Using Theorem 2 and Corollary 5 the MADB is 0.8695 s. The same result can be obtained using the LMI method as reported in [7, 23, 24, 30]. In [11, 17], the value reported for MADB is \(4.5 \times 10^{-4}\) s and in [22] it is 0.0538 s. In [29], the MADB is 0.785 s. It has been reported in [10], where an improved Lyapunov-Krasovskii approach has been used, that the MADB is 1.0551 s and also 1.05 s reported in [23] with improved algorithm for solving the LMI. In [1], the MADB is 1.0081 s. Using the proposed method with second order finite difference approximation we can obtain 1.13 s as the MADB. The system response with 0.8695 s time delay and \(x(0) = [0.1 0]^{T}\) is shown in Figure 4 which proves the system is stable with the estimated MADB.

**Example 8** (see [31]). Consider

\[
\dot{x}(t) = \begin{bmatrix} 0 & 1 & 0 \\ 0 & 0 & 1 \\ 0 & -2 & -3 \end{bmatrix} x(t) + \begin{bmatrix} 0 \\ 0 \\ 1 \end{bmatrix} u(t), \\
\end{equation}

\[
u(t) = \begin{bmatrix} -160 \\ -54 \\ -11 \end{bmatrix} x(t). \tag{55}
\]

For this third-order system both the LMI and our method give 0.0909 s as the MADB. Also with Corollary 5 the MADB is 0.0909 s.

**Example 9** (see [31]). The last example is the fourth-order model of the inverted pendulum shown in Figure 5 which is in many papers reduced to a second order system in order to verify the stability of NCSs. The pendulum mass is denoted by \(m\) and the cart mass is \(M\); the length of the pendulum rod is \(L\). The open loop system is unstable. The states are defined as \(x_1 = x, x_2 = \dot{x}, x_3 = \theta,\) and \(x_4 = \dot{\theta}\). The model is given by

\[
\dot{x}(t) = \begin{bmatrix} 0 & 1 & 0 & 0 \\ 0 & 0 & -mg & 0 \\ 0 & 0 & M & 0 \\ 0 & 0 & (M+m)g & mL \end{bmatrix} x(t) + \begin{bmatrix} 0 \\ 0 \\ 1 \\ M \end{bmatrix} u(t), \tag{56}
\]

\[
y(t) = \begin{bmatrix} x \\ \theta \end{bmatrix} = \begin{bmatrix} 1 & 0 & 0 \\ 0 & 0 & 1 \end{bmatrix} x(t). \]

The parameters used are \(M = 2\) kg, \(m = 0.1\) kg, and \(L = 0.5\) m. Then the linear model becomes

\[
\hat{x}(t) = \begin{bmatrix} 0 & 1.000 & 0 & 0 \\ 20.601 & 0 & 0 & 0 \\ -0.4905 & 0 & 0 & 0 \end{bmatrix} x(t) + \begin{bmatrix} 0 \\ 0 \\ 1 \\ 0 \end{bmatrix} u(t). \tag{57}
\]

Using the LQR Matlab function with \(Q = I\) and \(R = 1\), the controller is given by

\[
K_{\text{LQR}} = \begin{bmatrix} 52.1238 & 11.5850 & 1.000 & 2.7252 \end{bmatrix}. \tag{58}
\]

Using the LMI method the MADB is 0.0978 s and our method gives 0.0978 s using Theorem 2 and Corollary 5. We noted that there is a good agreement between our method and the LMI method because \(\tau\) is small enough to make the finite difference approximation hold. The system response with 0.0978 s time delay and with \(x = 0\) and \(\theta = 0.1\) is shown in Figure 6 which shows the system is stable. Many examples have been studied to compare the results obtained using the method proposed in this paper with the results obtained using the LMI method [7] and the fourth-order Pade approximation method. The calculation results are summarized in Table 1 along with the simulation based MADB.

**Remarks.** From Table 1, it can be seen that the proposed new method can give values of MADB similar to the values obtained using the LMI method and the other methods; however, the method proposed in this paper has a much
Table 1: The MADB (seconds) using the proposed method with 1st, 2nd, and 3rd order finite difference approximation for the delay term, the LMI method, the fourth-order Padé approximation method, and the simulation based method.

The application of the finite difference approximation for representing the time delay is not new but we found in this paper that using higher order approximations can sufficiently represent the time delay linear system. From Table 1 it can be concluded that using the first order approximation the estimated MADB is comparable with the other two methods. This is because the derivation of the linear model from the nonlinear model is based on neglecting the higher order derivative terms. In some cases we need to use the higher derivative terms for the time delay in order to achieve more accurate results for the MADB. The current research is to derive sufficient conditions for applying the method in order to find the tolerance of the estimated MADB.

4. Concluding Remarks

The main contribution of the paper is to have derived a new method for estimating the maximum time delay in NCSs. The most attractive feature of the new method is that it is a simple approach and easy to be applied, which can be easily interpreted to design engineers in industrial sectors. The results obtained in this method are compared with those obtained through the methods introduced in the literature. The method has demonstrated its merits in using less computation time due to its simple structure and giving less conservative results while showing good agreement with other methods. The method is limited to linear systems only and the work for extending the method for a class of nonlinear systems is on-going.

Conflict of Interests

The authors declare that there is no conflict of interests regarding the publication of this paper.
