Hydrogen sulfide (H₂S), produced endogenously by the activation of two major H₂S-generating enzymes (cystathionine β-synthase and cystathionine γ-lyase), plays important regulatory roles in different physiologic and pathologic conditions. The abnormal metabolism of H₂S is associated with fibrosis pathogenesis, causing damage in structure and function of different organs. A number of in vivo and in vitro studies have shown that both endogenous H₂S level and the expressions of H₂S-generating enzymes in plasma and tissues are significantly downregulated during fibrosis. Supplement with exogenous H₂S mitigates the severity of fibrosis in various experimental animal models. The protective role of H₂S in the development of fibrosis is primarily attributed to its antioxidation, antiapoptosis, anti-inflammation, proangiogenesis, and inhibition of fibroblasts activities. Future studies might focus on the potential to intervene fibrosis by targeting the pathway of endogenous H₂S-producing enzymes and H₂S itself.

1. Introduction

Hydrogen sulfide (H₂S), known for decades as a noxious and toxic gas, has been recognized recently as a third gasotransmitter, together with its two counterparts nitric oxide (NO) and carbon monoxide (CO) [1]. H₂S plays important regulatory roles in different physiologic and pathologic conditions, including hypertension, angiogenesis, neurodegenerative diseases, inflammation, and metabolic syndrome, to name a few [2]. H₂S is endogenously generated in various tissues through the transsulfuration pathway by two pyridoxal-5’-phosphate-dependent enzymes, cystathionine β-synthase (CBS) and cystathionine γ-lyase (CSE), with L-cysteine and homocysteine (Hcy) as the substrates. Besides, 3-mercaptopropionate sulfurtransferase (MST) may produce H₂S through the cooperation with cysteine aminotransferase [1, 2].

Fibrosis is a complicated process, in which the tissue repair after injury is too strong or out of control, and thus results in excessive formation of fibrous connective tissue. This process could be triggered by various factors such as inflammation, immunity, toxicant, ischemia, or hemodynamic changes [3]. Fibrosis can occur in multiple tissues or organs including lung, heart, liver, and kidney. The main pathologic changes of fibrosis are the increased fibrous connective tissue and decreased parenchymal cells, which can cause organ structural damage, functional decline, and even failure, seriously threatening to human health [4].

Previously, H₂S was considered as a toxic environmental pollutant, which can cause early lung damage, chronic lung inflammation, and pulmonary fibrosis [5, 6]. However, the physical role of H₂S in the development of fibrosis has attracted significant attention recently. Numerous studies have demonstrated that endogenous and exogenous H₂S play a critical role in the development of fibrosis in lung [7–10], liver [11–13], kidney [14, 15], and heart [16–18]. This review focuses on the protective roles of H₂S in fibrosis pathogenesis.
2. Altered Endogenous H$_2$S/Its Producing Enzymes in Fibrosis Pathogenesis

The H$_2$S-producing enzymes/endogenous H$_2$S pathways are involved in the development of fibrosis. The deficiency in endogenous CBS/H$_2$S or CSE/H$_2$S system is responsible for fibrosis [8, 19]. Downregulation of CBS and CSE expression/activity and decreased plasma H$_2$S levels were observed in patients with hepatocirrhosis [20–23]. And animal models of various organ fibrosis demonstrated the significant decrease of the endogenous H$_2$S level in plasma and tissues and the H$_2$S-producing enzymes, whereas the administration exogenous H$_2$S could inhibit the fibrosis development [9, 13, 15, 18, 19, 24, 25].

2.1. H$_2$S and Pulmonary Fibrosis. Pulmonary fibrosis, a chronic and progressive interstitial lung disease, is triggered by various factors like organic and inorganic particles, chemicals, radiation, and infections. Its common steps are fibroblastic foci formation, exaggerated extracellular matrix (ECM) deposition, and eventually leading to the destruction of the lung parenchymal architecture [26–28]. The H$_2$S-producing enzymes (CSE, CBS, and/or MST) are expressed in human and animal lungs [29], and the physiologic plasma concentration of H$_2$S in healthy animals and humans ranges from 10 to 300 μmol/L [30, 31]. The alteration of H$_2$S-producing enzymes and endogenous H$_2$S levels are associated with the development of pulmonary fibrosis. In a rat model of bleomycin- (BLM-) induced pulmonary fibrosis, plasma H$_2$S content and lung tissue CSE activity (H$_2$S production rate) in experimental groups were downregulated by 44% and 27%, respectively, on day 7, while the CSE mRNA level in the lungs treated with BLM was 34% and 143% higher than that in controls on day 7 and day 28, respectively. These results may be due to the compensatory mechanism for the decreased H$_2$S in the body [9]. The lung hydroxyproline content, as a marker of collagen deposition, was increased by 43% in BLM-treated group on day 7 and 100% on day 28, along with histologic changes of inflammatory cells infiltration, fibroblast proliferation, and collagen deposition, whereas intraperitoneal injection of sodium hydrosulfide (NaHS, 1.4 and 7 μmol/kg body weight, resp.) twice a day decreased the hydroxyproline content and remarkably attenuated the severity of lung fibrosis [9]. These results were further supported by Cao et al. [10] and Li et al. [32]. Consistent with the BLM-induced pulmonary fibrosis, reduced endogenous H$_2$S levels in plasma and lung tissue were observed in another rat model of passive smoking-induced pulmonary fibrosis, accompanied by the upregulation of type I collagen expression and the occurrence of typical histopathological changes of pulmonary fibrosis, whereas NaHS administration at 8 μmol/kg once daily remarkably upregulated H$_2$S level and inhibited the passive smoking-induced pulmonary fibrosis [28].

According to the above mentioned studies, exogenous H$_2$S (NaHS) is considered to have protective effect against pulmonary fibrosis at a relatively low dose from 1.4 μmol/kg body weight twice daily to 28 μmol/kg once daily [9, 10, 28, 32]. However, high concentrations of H$_2$S (50–500 ppm) can cause bronchiolitis obliterans (BO) and pulmonary edema and eventually lead to chronic inflammation and pulmonary fibrosis [2, 6, 33]. Except the protective role of H$_2$S proved by extensive studies including animal models and in vitro experiments [7–10, 28, 32, 34], the altered expression of endogenous H$_2$S-producing enzymes and the levels of endogenous H$_2$S in patients with pulmonary fibrosis are unknown yet.

2.2. H$_2$S and Hepatic Fibrosis. Similar to pulmonary fibrosis, hepatic fibrosis is a dynamic process in response to a variety of stimuli such as ethanol, viral infection, and toxins, leading to the destruction of the architecture of liver parenchyma, followed by excessive ECM deposition, fibrous tissues formation, and cirrhosis (the final pathological stage of hepatic fibrosis) [35, 36]. Three endogenous H$_2$S-producing enzymes (CSE, CBS, and MST) are all present in the liver [37]. CSE is expressed in the cytosol of hepatocytes, hepatic stellate cells (HSCs), hepatic artery, portal vein, and the terminal branches of the hepatic afferent vessels, while CBS is mainly expressed in the cytosol of hepatocytes, hepatic artery, and portal vein [2, 38]. MST is predominantly localized in mitochondria and cytosolic fractions of pericentral hepatocytes [39]. CSE and CBS are the primary contributors to H$_2$S production in the liver [40]. Under physiological conditions, CSE accounts for 97% of the H$_2$S output in liver [40]. The metabolic levels of H$_2$S and its producing enzymes were observed to change in human hepatic fibrosis and cirrhosis, as well as in animal and cellular models of hepatic fibrosis [11, 13, 20, 23, 38, 41]. In patients with cirrhosis-induced portal hypertension, plasma H$_2$S levels were significantly lower than healthy controls and correlated inversely with the disease severity by Child-Pugh score (42.6 ± 4.7 μmol/L, 33.5 ± 7.7 μmol/L, and 22.2 ± 7.9 μmol/L in group Child-Pugh score of A, B, and C, resp., but 43.5 ± 6.2 μmol/L in control group) [20]. This decrease stemmed from a reduction of CBS and CSE expression/activity [21–23, 42]. Whether schistosomiasis cirrhosis-induced portal hypertension (SPH) model of rabbit or bile duct ligation- (BDL-) or carbon tetrachloride- (CCL$_4$-) induced cirrhosis model of rat, both revealed reduced H$_2$S level in serum and liver tissues by 20% to 80% [13, 20, 38, 41] and decreased CSE protein expression by approximately 30% to 80% [13, 20, 38, 43]. Meanwhile, plasma H$_2$S concentrations showed a clear descending trend during the progression of cirrhosis [13, 20]. These results suggest that endogenous H$_2$S generated by H$_2$S-producing enzymes might involve the pathogenesis of human and animal hepatic fibrosis.

To further prove the protective role of endogenous H$_2$S, the effects of exogenous H$_2$S supplementation in the progress of hepatic fibrosis were investigated in animal models [11–13, 38, 44]. NaHS administration significantly elevated the serum levels of H$_2$S, decreased the portal pressure, attenuated hyaluronic acid level (HA, a serum fibrosis index), downregulated hepatic hydroxyproline content, reduced the number of collagenous fibers, and eventually alleviated the pathologic features of hepatic fibrosis induced by schistosomiasis, bile duct ligation, or carbon tetrachloride in animal models.
For example, in cirrhotic rats induced by CCl$_4$, intraperitoneal injection with NaHS (10 μmol/kg body weight, every two days for 12 weeks) significantly elevated the serum levels of H$_2$S by an average of about 1.33-fold, reduced the mean level of serum HA by 38.6%, decreased both the number of collagenous fibers and the hydroxyproline content in livers by 40%, downregulated the alpha-smooth muscle actin (α-SMA, a marker of fibrosis) by 50%, and reduced the portal pressure by about 30% [13]. Similarly, NaHS inhibited CCl$_4$-induced liver fibrosis in rats at a dosage of 56 μmol/kg body weight once daily. In vitro, HSCs isolated from BDL-cirrhosis rats had a 40% downregulated CSE expression and an 80% drop of H$_2$S production [38]. Besides, Fan et al. [11, 12] investigated the effects of exogenous H$_2$S on HSCs activation by ferric nitrotriacetate (Fe-NTA, 500 μg/L) and found that incubation with various concentrations of NaHS (0, 100, 200, or 500 μmol/L) resulted in a dose-dependent inhibition in HSC proliferation and induction of GI phase cell cycle arrest and a downregulated expression of collagen I protein.

These researches above indicate that H$_2$S plays a protective role against hepatic fibrosis at a low level of 10–56 μmol/kg/day [13, 38, 44], while high concentration of H$_2$S may cause hepatotoxicity [37, 45]. Exposure to a deadly concentration of H$_2$S (500–1000 ppm) caused abnormal liver function (elevated ALT and AST) in human, as reported previously [46]. Animal studies also demonstrated different degrees of hepatic damage such as enlarged pale livers and severe hyperemia after H$_2$S exposure at high concentrations (63 to 500 ppm) [33].

2.3. H$_2$S and Renal/Kidney Fibrosis. Renal fibrosis, including glomerular sclerosis and tubulointerstitial fibrosis, is the hallmark of progressive renal disease of virtually any etiology such as glomerular hyperfiltration, hyperperfusion and hyperpressure, and ischemia/reperfusion injury. It is characterized by renal parenchymal cells injury and death, interstitial inflammatory cells infiltration, fibroblasts proliferation and myofibroblast transformation, excessive ECM deposition, and fibrogenesis [47, 48]. Similar to liver and lung, renal tissues express all the three endogenous H$_2$S-producing enzymes [39]. CBS is predominantly expressed in renal proximal tubules, while CSE is mainly located in renal glomeruli, proximal tubules, interstitium, and interlobular arteries [14]. Besides, MST is also localized in proximal tubular epithelium in the kidney [39]. CBS and CSE are abundant in renal tissues and produce H$_2$S in kidney in a combined manner [49]. Under normal physiological conditions, the expression of CSE protein in kidney is 20-fold higher than that of CBS, appearing to be the main H$_2$S-forming enzyme in the kidney [2, 40].

The alterations of endogenous H$_2$S metabolism and its producing enzymes in renal fibrosis are well studied in in vivo models [14, 15, 19, 50, 51]. Unilateral ureteral obstruction- (UUO-) induced model is a commonly used experimental model for renal interstitial fibrosis, which can be easily manipulated with respect to timing, severity, and duration through surgical intervention [47]. After unilateral ureteral obstruction, CBS and CSE expressions in ureteral obstructive mice kidneys were gradually downregulated in a time-dependent pattern, consistent with decreased plasma and tissue H$_2$S levels and aggravated interstitial fibrosis in the kidney after UUO [15, 19]. For instance, the protein expression was downregulated by 30.3%, 62.1%, and 70.5% on days 7, 14, and 21 for CBS, respectively, and decreased by 27.2%, 58.2%, and 74.1% for CSE, accompanied by the time-dependent decrease in plasma H$_2$S level by 10.56%, 11.76%, and 22.01% after UUO [19]. Accordingly, the area of tubulointerstitial fibrosis was increased by 13.11-fold on day 7, by 31.35-fold on day 14, and by 55.33-fold on day 21, respectively [19]. Song et al. [14] found that the CBS expression was nearly completely ablated by obstructive injury on day 14, but CSE was increased when compared to the contralateral kidney. Meanwhile, H$_2$S production in the obstructed kidney or in plasma was dramatically reduced, along with a significant accumulation of collagen fibrils and an enhanced renal expression of α-SMA and fibronectin on day 14 after operation [14]. Notably, the increase in CSE expression in obstructive kidney could be explained by a “compensatory mechanism” as mentioned by the author, attempting to maintain the H$_2$S level [14]. These results suggest that the expression of H$_2$S-producing enzymes and H$_2$S levels in obstructive kidney and plasma reflect the severity of renal interstitial fibrosis in the UUO-induced model. Thus, the endogenous plasma H$_2$S might be an ideal biomarker for renal fibrosis.

UUO-induced animal model revealed that exogenous H$_2$S could impact the development of renal fibrosis [14, 15, 19, 52]. For instance, Zhao et al. [19] demonstrated that intraperitoneal injection with NaHS (1.4 or 70 μmol/kg, twice daily immediately after operation) significantly increased plasma and tissue H$_2$S concentration in the obstructive kidney and decreased the area of renal tubulointerstitial fibrosis. Jiang et al. [52] also found that NaHS treatment (89 μmol/kg, i.p. injection once daily, 3 days before surgery and there-after continuously for 9 days) reduced the development of interstitial fibrosis and the fibrous area in the obstructed kidneys. In addition, NaHS administration also alleviated the pathological changes of renal fibrosis in other models of renal injury triggered by gentamicin-induced nephrotoxicity [53] or streptozotocin-induced diabetic nephropathy [50, 51]. However, the metabolic changes of H$_2$S and its producing enzymes as well as its therapeutic potentials in patients with renal fibrosis need to be further studied.

2.4. H$_2$S and Cardiac Fibrosis. Cardiac fibrosis is a pathological process initiated by some harmful stimuli such as myocardial injury, mechanical stretch, and inflammatory stimuli and followed by the proliferation and migration of cardiac fibroblasts and myofibroblasts transdifferentiation. This process then causes excessive ECM deposition and abnormalities in cardiac structure and function including hypertrophy, failure, and arrhythmias [54, 55]. In mammals, CSE is abundant in heart, vascular smooth muscle, and vascular endothelial cells and is the most relevant H$_2$S-producing enzyme in the cardiovascular system [56, 57]. CBS
mRNA has been found in endocardium cells and atrial and ventricular myocardial cells [58], yet its protein expression is actually rare in mammalian cardiovascular system [2]. MST is predominantly localized in cardiomyocytes in the heart and in the vascular endothelium, but its contribution to H$_2$S production is significantly lower [39, 59].

Growing evidence has suggested that endogenous H$_2$S and its producing enzymes involve the development of cardiac fibrosis. Enzymes expressions including CSE and CBS and endogenous H$_2$S levels were reduced in different animal models of cardiac fibrosis [17, 25, 60–62]. Simultaneously, decreases in endogenous H$_2$S and its producing enzymes were negatively correlated with the severity of cardiac fibrosis [17, 25, 60–62]. For instance, endogenous H$_2$S concentration in plasma decreased by about 15% in a rat model of cardiac fibrosis induced by pressure overload, and the hydroxyproline content in the cardiac tissue increased by about 65%, with an extensive deposition of collagen in the left ventricle (LV) tissue [25]. In volume overload-induced mouse model of cardiac fibrosis, endogenous H$_2$S production and CSE protein expression in the heart were reduced by 60–80% and 35%, respectively, while the expressions of matrix metalloproteinase-2/9 (MMP-2/9) and tissue inhibitors of metalloproteinase-1 (TIMP-1/3) were robustly increased, along with a 1.24-fold rise of total hydroxyproline and an increase in collagen deposition [17, 60]. The similar alterations of endogenous H$_2$S-producing enzymes and H$_2$S were also seen in mouse model of cardiac fibrosis mediated by myocardial infarction induced by ligation of left anterior descending coronary artery. For example, the expressions of CSE and CBS proteins in hearts were decreased by about 80% and 60%, respectively, after myocardial infarction [62], and the plasma H$_2$S concentration was significantly decreased to 53.3 ± 2.7 μmol/L compared to the controls (65.1 ± 1.5 μmol/L), while the percentage of fibrosis size to total area of left ventricle in rats of myocardial infarction was more than twofold higher than that in controls (25.7 ± 1.2% versus 12.5 ± 0.5%; $P < 0.01$) [61].

The protective effect of exogenous H$_2$S in cardiac fibrosis has been demonstrated in various animal models [17, 18, 25, 60–66]. In a model of spontaneously hypertensive rats (SHR), chronic treatments with NaHS (i.p. 10, 30, and 90 μmol/kg/day, for 3 months) were all effective in reducing indexes of perivascular and interstitial fibrosis in the heart including perivascular collagen area-to-luminal area ratio (PVCA/LA) and collagen volume fraction (CVF) [65]. In pressure overload-induced heart failure model of mouse by transthoracic or abdominal aortic banding, administration of NaHS (po, 30 μmol/L, or i.p. 14 μmol/kg/day) significantly upregulated the levels of endogenous H$_2$S in plasma and reduced the deposition of collagen in perivascular and intracardiac parenchymal tissue [25, 64]. Similarly, NaHS (30 μmol/L) or sodium thiosulfate (Na$_2$S$_2$O$_3$, 3 mg/mL) ameliorated the decreased CSE expression, normalized the reduced H$_2$S production, mitigated the expressions of MMP-2/9 and TIMP-1/3, and then attenuated the collagen deposition in LV tissues in a volume overload-induced heart failure model of mouse [17, 60]. The role of exogenous H$_2$S in alleviating cardiac fibrosis is also confirmed in the mouse model of myocardial infarction induced by ligation of left anterior descending coronary artery [18, 61, 62, 66]. In the NaHS-treated group of rats after myocardial infarction, H$_2$S concentration in plasma, CSE protein content, and mRNA expression in LV myocardium were all significantly increased, compared with vehicle-treated group (69.5 ± 4.6 μmol/L versus 53.3 ± 2.7 μmol/L for plasma H$_2$S level, 0.66 ± 0.04 versus 0.51 ± 0.03 for CSE protein, and 0.94 ± 0.03 versus 0.72 ± 0.03 for CSE mRNA, resp.) [61]. Simultaneously, NaHS supplementation prevented the increase of MMP-2 and MMP-9 expression in the border zone of infracted tissues on day 14 [18] and decreased ratio of the fibrosis size to total area of LV at the end of the 6th week, compared with vehicle-injected controls (12.5 ± 0.5% versus 25.7 ± 1.2%) [61].

### 3. Protective Mechanisms of H$_2$S in the Development of Fibrosis

#### 3.1. H$_2$S and Oxidative Stress

Oxidative stress, resulting from an increased production of free radicals including reactive oxygen and nitrogen species (ROS and RNS) and an overwhelmed antioxidant defense system, plays a prominent role in the progression of fibrosis [17, 67–70]. ROS mainly consists of superoxide anion, hydroxyl radical (HO$^·$), and hydrogen peroxide, and RNS mainly consists of nitric oxide, nitrogen dioxide, and peroxynitrite. There are two kinds of antioxidant system in our body: one is enzymatic antioxidant system including superoxide dismutase (SOD), catalase (CAT), glutathione peroxidase 1 (GPx1), heme oxygenase 1 (HO-1), and NAD(P)H: quinone oxidoreductase 1 (NQO1). The other is nonenzymatic antioxidant system, including vitamin C, vitamin E, glutathione (GSH), thio-redoxin-1 (Trx-1), melanin, α-lipoic acid, carotenoids, and trace elements (copper, zinc, and selenium).

Growing evidence has suggested that endogenous H$_2$S has a protective effect against oxidative stress. H$_2$S reduces the intracellular redox environment and alleviates oxidative stress-induced damage. Given the important role of oxidative stress in the pathogenesis of fibrosis, it is reasonable to suspect that endogenous H$_2$S/H$_2$S-producing enzymes pathway inhibits the development of fibrosis by its antioxidative action.

In animal models of lung fibrosis, bleomycin stimulated inflammatory cells to generate excess ROS and then promoted oxidative stress such as lipid peroxidation (LPO), resulting in activation of profibrotic mediators like PAR-2 and MMPs 2/9, apoptosis of epithelial cell, and accumulation of collagen, thus leading to pulmonary fibrosis [71, 75, 76]. NaHS administration attenuated lung malondialdehyde (MDA, a marker of tissue fibrosis) and hydroxyproline formation in a rat model of bleomycin-induced pulmonary
fibrosis [9]. In another rat model of pulmonary fibrosis induced by chronic cigarette smoke exposure, H$_2$S could significantly decrease cigarette smoking-induced oxidative stress-related indexes like MDA and ROS in serum and lung tissue and enhance the activities of serum SOD and GPx, which is associated with the activation of nuclear factor E2-related factor (Nrf2) and the upregulation of HO-1 and Trx-1 proteins in the lungs [28]. In CCl$_4$-induced animal model of cirrhosis and Fe-NTA-induced in vitro model of hepatic fibrosis, the overproduction of ROS triggers lipid peroxidation, along with deficient antioxidants such as GSH, causes the imbalance between oxidative stress and antioxidant defense, and finally promotes HSCs proliferation and collagen synthesis in liver [II–13, 44, 68, 77]. Exogenous H$_2$S inhibits the Fe-NTA-induced elevation of intracellular ROS level and inhibition of proliferation of HSC cells, attenuates the CCl$_4$-induced elevation of hepatic MDA level, and decreases in hepatic GSH level, resulting in the reduction of collagen deposition in liver tissue, which are related to the inhibition of phosphorylated p38 MAPK (mitogen-activated protein kinase) and activation of phospho-Akt signaling pathway [11–13]. Similarly, exogenous H$_2$S supplement reversed these pathophysiological changes of fibrosis in kidney in animal models through inhibition of oxidative stress and recovery of antioxidant defense system, which may be attributed to the activation of Nrf2 and the upregulation of its downstream targets including HO-1 and NQO1 proteins in the renal tissue [15, 51–53].

In cardiac fibrosis induced by chronic volume/pressure overload or persistent hyperglycemia, H$_2$S ameliorates oxidative stress, decreases levels of MMP-2/9, TIMP-1/3, and ADAM-12, and increases the levels of TIMP-4 and β1-integrin [17, 59, 60, 63–65]. In addition, H$_2$S itself and the increased H$_2$S-derived thiols (principally GSH) are involved in the maintenance of enzymatic activation of antioxidant enzymes (e.g., CAT and SOD) in the myocardium [63, 65, 66]. NADPH oxidase 2 and NADPH oxidase 4 (Nox2 and Nox4), as a major source of ROS, play a critical role in profibrotic responses in cardiac fibroblasts and ischemic myocardium; moreover, Nox-generated ROS can mediate the conversion of fibroblasts into myofibroblasts via an extracellular signal-regulated kinase 1/2- (ERK1/2-) dependent signaling pathways; exogenous H$_2$S significantly inhibits cardiac Nox2/4 expression, ROS generation, and ERK1/2 phosphorylation [18, 78].

In short, H$_2$S can prevent the development of fibrosis by regulating the balance between oxidation and antioxidation and the detailed mechanisms underlying its antioxidant and antifibrotic effects involve the inhibition of phosphorylated p38 MAPK and Nox4-ROS-ERK1/2 signaling pathway and the activation of phospho-Akt and Nrf2-induced antioxidant signaling pathway [9, II–13, 15, 17, 18, 28, 51–53, 74, 78].

3.2. H$_2$S and Inflammation. Inflammation has been reported to be the initial stage in the development of fibrosis [79, 80], which causes parenchymal cells apoptosis, fibroblasts proliferation, and ECM deposition, ultimately leading to irreversible fibrotic injury [81, 82]. Treatment with H$_2$S significantly decreases the infiltration of inflammatory cells, downregulates proinflammatory cytokines like inducible nitric oxide synthase (iNOS), tumor necrosis factor-α (TNF-α), interleukin-1 (IL-1), IL-4, IL-6, and IL-8, and then inhibits the progression of fibrosis [10, 13–15, 18, 28, 51, 52, 78].

Inflammatory responses are associated with pulmonary fibrosis [79]. In the process of pulmonary fibrosis induced by bleomycin, different inflammatory cells including neutrophils and eosinophils appeared in the alveoli and interstitium at the early stage, followed by foci of collagen deposition, while large area of fibrosis instead of inflammatory infiltration was observed at the late stage [10]. Similarly, significant fibrosis and inflammatory cell infiltrations also emerged in the lung of smoking rats [28]. Nuclear factor-kappa B (NF-κB) regulates the generation of a lot of proinflammatory cytokines including high-sensitivity C-reactive protein (hs-CRP), TNF-α, IL-1, IL-6, and IL-8 and promotes the proliferation of fibroblast and the formation of fibrosis [10, 28, 75, 83]. MAPK, which consists of three major members, ERK1/2, c-Jun N-terminal kinase (JNK), and p38, also plays an important role in regulating inflammation and fibrosis [84]. In addition, Th1/Th2 balance may play a vital role in the processes of inflammation and fibrosis, as Th2 cytokines such as IL-4 mediate inflammatory response and then enhance the fibrotic process by augmenting fibroblasts proliferation and collagen production, while Th1 cytokines like interferon-γ (IFN-γ) have inhibitory effects on fibroblast proliferation and collagen synthesis [85]. Studies have demonstrated that H$_2$S can suppress the expression of NF-κB p65 and inflammatory markers like hs-CRP, TNF-α, IL-β, and IL-6, inhibit the phosphorylation of MAPKs, and regulate Th1/Th2 balance by elevating the ratio of IFN-γ/IL-4, thus alleviating inflammation and delaying the progression of pulmonary fibrosis [10, 28].

Chronic inflammation and the associated regenerative wound healing responses are strongly associated with the development of hepatic fibrosis and cirrhosis [86]. CCl$_4$-induced cirrhotic rats showed significantly high levels of serum proinflammatory cytokines including TNF-α, IL-1β and IL-6, and soluble ICAM-1 (intercellular cell adhesion molecule-1), while simultaneous administration of NaHS resulted in a significant decrease of these cytokines, along with alleviated collagenous fibers in the liver [13]. Interstitial inflammation plays an important role in the priming and progression of renal fibrosis as it can induce apoptosis in tubular cells and promote extracellular matrix production, fibroblast proliferation, and epithelial to mesenchymal transition [80, 81]. Exogenous H$_2$S was found to mitigate the renal interstitial inflammatory response through the inhibitions of NF-κB and MAPKs signal pathways and then result in fibrogenesis suppression in kidney [14, 15, 51]. Similarly, supplementation with exogenous H$_2$S significantly decreased mRNA and protein levels of inflammatory biomarkers (iNOS, TNF-α, ICAM-1, and VCAM-1 (vascular cell adhesion molecule-1)) in the border zone of infarcted myocardium tissues and also reduced granulocyte influx into necrotic areas to some extent [18, 78]. Furthermore, studies demonstrated that the heat shock protein “HO-1” had an inhibitory effect on the inflammatory and fibrotic responses in injured myocardium and
H₂S therapy markedly increased HO-1 protein expression in both the ischemic heart and angiotensin II- (Ang II-) stimulated cardiac fibroblasts, accompanied by ameliorative cardiac fibrosis and inflammation in ischemic myocardium [18, 87].

Taken together, H₂S may exert its anti-inflammatory and antiﬁbrotic effect through inhibiting the activation of NF-κB and MAPKs (p38, JNK, and ERK), as well as upregulating the ratio of Th1/Th2 and the expression of HO-1 protein [10, 14, 15, 17, 28, 51, 87].

3.3. H₂S and Fibroblasts. Numerous studies have shown that fibroblasts proliferation, migration, and differentiation to myofibroblasts, along with excessive ECM production, are key events of fibrosis [18, 47, 88–91]. H₂S could mediate these inhibitory effects by suppressing the activation of proliferation-related genes, protein kinases, signalling pathways, and ion channels [7, 8, 11, 14, 16, 18, 44]. The migration, proliferation, and myofibroblasts transdifferentiation of lung ﬁbroblasts like MRC5 cells, as well as epithelial-mesenchymal transition (EMT) of alveolar epithelial cells like A549 cells, are closely associated with the pathogenesis of pulmonary ﬁbrosis [7, 8]. Studies have reported that incubation with H₂S signiﬁcantly inhibited the proliferation, migration, and myofibroblasts differentiation of MRC5 cells and the EMT of A549 cells through suppressing ERK phosphorylation and (transforming growth factor beta-1) TGF-β1-Smad2/3 signaling pathways [7, 8, 92]. In the process of liver ﬁbrosis, HSCs are characterised by a transformation from quiescent vitamin A-rich cells to myofibroblasts with enhanced proliferation, ﬁbrogenesis and ECM synthesis, and contractility [89]. NaHS treatment could alleviate hepatic ﬁbrosis by reducing the contractility of HSCs and attenuating ECM deposition through the downregulation of calcium inﬂux and collagen I protein expression in activated HSCs [11]. In addition, TGF-β1 is a profibrogenic agent in liver injury and hepatic ﬁbrosis [93, 94]. Shen et al. [44] elucidated that exogenous H₂S could downregulate TGF-β1 expression, prevent HSC activation and proliferation, reduce ECM synthesis, and consequently have antiﬁbrosis effect on liver. For renal ﬁbroblasts, NaHS decreased the cell number and the DNA synthesis of normal rat kidney ﬁbroblasts (NRK-49F), which was associated with the decreased expressions of proliferation-related genes including proliferating cell nuclear antigen (PCNA) and c-Myc [14]. NaHS treatment blocked the transdifferentiation of quiescent renal ﬁbroblasts and tubular epithelial cells into myofibroblasts by inhibiting the TGF-β1/Smad3 and MAPKs (ERK, p38, and JNK) signaling pathways in the UUO-induced kidney ﬁbrosis models [14, 15, 95]. Similarly, exogenous H₂S was found to suppress Ang II-mediated cardiac ﬁbroblast activation and profibrotic activity by repressing Nox4-ROS-ERK1/2 signaling pathway [18]. In addition, NaHS effectively reduced proliferation and myofibroblast transformation of atrial ﬁbroblasts via inhibition of TGF-β1 function and the activities of BKCa, IKS, and IKCa channels [16].

The inhibitory effects of H₂S on these ﬁbroblasts activation and the underlying mechanisms are summarized as follows: (1) H₂S downregulates the expressions of proliferation-related genes including PCNA and c-Myc, which are associated with its antiproliferative effect [14]; (2) H₂S reduces the phosphorylation of MAPKs (p38, JNK, and ERK), increases the phosphorylation of Akt, and thus further suppresses ﬁbroblasts proliferation and migration [7, 8, 12, 51]; (3) H₂S inhibits myofibroblast transformation of ﬁbroblasts with blockade of TGF-β1-Smad signaling pathway [14, 16, 44, 50, 51, 96]; (4) H₂S suppresses ﬁbroblasts activation by repressing Nox4-ROS-ERK1/2 signaling pathway [18]; (5) H₂S negatively modulates the activity of calcium and potassium channels through downregulating Ca²⁺ influx, large conductance Ca²⁺-activated K⁺ current (BKCa), transient outward K⁺ current (Ito), and inwardly rectifying K⁺ current (IKir) in ﬁbroblasts and then reducing ﬁbroblast proliferation and myofibroblast transdifferentiation [11, 16, 97, 98].

3.4. H₂S and Apoptosis. H₂S has both a proapoptotic effect on ﬁbroblasts and an antiapoptotic effect on parenchymal cells, which depends on the regulation of cell cycle, apoptotic-related factors, and apoptotic signaling pathways, thus interfering with the progress of ﬁbrosis [11, 17, 34, 52, 61, 64, 66]. During the normal wound healing, the number of ﬁbroblasts is reduced through apoptosis [96]. However, it has been reported that ﬁbroblast is resistant to Fas-mediated apoptosis in the process of pulmonary ﬁbrosis [99]. Baskar et al. [34] found that H₂S propelled MRC5 ﬁbroblast cells towards apoptotic death by inducing DNA damage and cell cycle arrest at G1 phase and activating various apoptosis-related factors, such as p53, p21, ku70, ku80, Bax, and cytochrome c.

In the pathogenesis and development of liver ﬁbrosis, cell cycle arrest and apoptosis of activated HSCs play an important role [11, 12, 100]. Fan et al. [11, 12] found that NaHS induced a signiﬁcant increase in the percentage of cells in the G1 phase, with a corresponding decrease in the percentage of cells in the S phase, indicating that NaHS inhibited HSC proliferation by inducing G1 phase arrest. Meanwhile, they discovered that Fe-NTA treatment increased the apoptotic rate of HSC-T6 cells, but NaHS administration led to two contradictory results. In the early stage of hepatic ﬁbrosis, oxidative stress contributed to the activation and transdifferentiation of quiescent HSCs and simultaneously promoted the proapoptotic activity of HSCs. And during this period, NaHS might inhibit apoptosis through antioxidant effect, with decreased phospho-p38 and increased phospho-Akt proteins [12, 35]. On the contrary, NaHS treatment resulted in a signiﬁcantly higher apoptotic rate in HSC-T6 cells treated with Fe-NTA in the later stage, which might be due to the increased oxidative stress [11, 12]. The above two phenomena are consistent with a previous study, which has shown that proapoptotic or antiapoptotic activity depends on the stage of ﬁbrosis [100].

H₂S propels ﬁbroblasts towards apoptosis by inducing DNA damage and cell cycle arrest at G0/G1 phase, as well as stimulating apoptosis-related factors including p53, p21, ku70, ku80, Bax, and cytochrome c [11, 34]. On the other hand, H₂S reduces parenchymal cells apoptosis by inhibiting TNF-α-mediated proapoptotic signaling pathway, regulating the MMP/TIMP axis, and elevating the ratio of...
antiapoptotic factors [insulin like growth factor-I (IGF-I), Bcl-2] to proapoptotic factors [Fas ligand (Fas-L), Bax, caspases, and cytochrome c], thus eventually leading to resistance to fibrosis [14, 17, 52, 61, 64, 66].

3.5. H₂S and Angiogenesis. As sensitive to anoxia and ischemia, the heart is the most liable to undergo dysfunction or failure after myocardial ischemia or infarction, accompanied by structural abnormalities including cardiomyocyte loss and myocardial fibrotic remodeling in peri-infarct and infarct area [18, 101]. Angiogenesis, referring to the spontaneous blood vessel formation and/or the growth of new blood vessels from preexisting vessels, is a complex biological process characterized by ECM remodeling as well as endothelial cell growth, migration, and assembly into capillary structures [2, 74]. As angiogenesis promotes the delivery of both oxygen and energy substrates for tissue repair after injury, it is vital for various physiological or pathological events, like normal growth and development, wound healing, or repair after myocardial infarction [2, 102]. Interestingly, previous studies have revealed that H₂S protects against fibrosis by a proangiogenic effect [62, 74, 103]. In different mouse models of cardiac fibrosis induced by myocardial infarction or pressure overload-mediated heart failure, exogenous H₂S supplement upregulated the expression of vascular endothelial growth factor (VEGF; a proangiogenic factor) and its receptors including tyrosine kinase receptor (flk-1) and fms-like tyrosine kinase (flt-1) as well as the phosphorylation of endothelial NO synthase (eNOS) and the bioavailability of NO but downregulated the expression of antiangiogenic factors such as endostatin, angiostatin, and parstatin, accompanied by augmented vascular density and reduced intermuscular and perivascular fibrosis in heart tissues [62, 74]. The proangiogenic effect of H₂S is associated with the proliferation and migration of endothelial cell through the activation of several cellular signaling pathways including the PI-3 K/Akt, the MAPKs (e.g., ERK1/2 and p38), ATP-sensitive potassium (K_ATP) channels, and VEGF–eNOS-NO pathway [74, 103]. Although exogenous H₂S inhibits the cardiac fibrosis partially by proangiogenic effect, no much evidence is from lung, liver, and kidney fibrosis.

These protective mechanisms of hydrogen sulfide in the development of fibrosis have been also depicted in Figure 1.

4. Concluding Remarks

In this review, we have demonstrated that endogenous or exogenous H₂S at a physiological or relatively low concentration plays a protective role in the development of fibrosis in lung, liver, kidney, and heart, with its antioxidant, antiapoptotic, anti-inflammatory, proangiogenic properties and its inhibitory effect on fibroblasts activation. These results imply that the endogenous H₂S-producing enzymes and H₂S pathway might be a potential therapeutic target for fibrosis. However, we still have a long way to go before a complete understanding of the physical functions of H₂S in fibrosis pathogenesis. The following issues serve only as examples.

(i) The degree in endogenous H₂S-producing enzymes and H₂S was related to the severity of fibrosis. Although it will be interesting to investigate further whether endogenous H₂S could be a promising biomarker for fibrosis, it appears to be premature to correlate the measured blood/tissue levels of H₂S with the severity of fibrosis or the related biological outcomes after H₂S treatment, as long as the real or exact blood and tissue H₂S concentrations are still unknown and/or undetectable due to the lack of appropriate techniques.

(ii) As fibrosis can occur in many tissues and organs with a similar pathogenesis, it is reasonable to speculate that endogenous H₂S-producing enzymes and H₂S would play an important role in all kinds of fibrosis in the body like pancreatic fibrosis and skin fibrosis.

(iii) Supplementation with exogenous H₂S such as NaHS not only directly increases H₂S levels in the body, but also keeps, restores, or even promotes the expression of endogenous H₂S-producing enzymes like CSE and CBS to produce endogenous H₁S [15, 18, 19, 50, 51, 60–62, 66]. This positive feedback mechanism is largely unknown and merits further investigation.

(iv) Although H₂S mitigates the fibrosis development through its antioxidant, antiapoptotic, and anti-inflammatory properties as mentioned above, the exact molecular mechanism is still unknown. Mustafa et al. [104] initially found that H₂S physiologically modified some proteins’ activation by S-sulfhydration. Similar to methylation or acetylation, S-sulfhydration is now recognized as another mode of posttranslational modification. Recent studies found H₂S can induce Keap1 s-sulfhydration, promote Nrf2 dissociation from Keap1, enhance Nrf2 nuclear translocation, and eventually stimulate mRNA expression of Nrf2-targeted downstream genes such as glutamate-cysteine ligase and GSH reductase to protect against oxidative stress-induced cellular senescence and ischemia/reperfusion injury [105, 106]. Given the important role of Nrf2 in oxidative stress and the development of fibrosis [28], it is reasonable to suspect that H₂S might modify the Keap1/Nrf2 pathway by S-sulfhydration to protect against fibrosis development.

(v) Recent research showed organ fibrosis is related to the decrease of autophagy [107, 108]. Impairment of autophagy by TGF-β1 or IL-17A promoted fibrogenesis in pulmonary fibrosis [107, 108], while autophagy activation via IL-17A blockade decreased the production of collagen, attenuated fibrosis, and increased survival in the murine model of bleomycin-induced fibrosis [108]. Autophagy plays a complex regulatory pathway in liver fibrosis, with profibrogenic effects relying on the activation of hepatic stellate cells, but with antifibrogenic properties via indirect hepatoprotective and anti-inflammatory properties, as also seen in kidney fibrosis [109–111]. These studies
imply that autophagy might involve the pathogenesis of fibrosis. Interestingly, H₂S can play its biologic roles via autophagy regulation. Exogenous H₂S can induce/enhance autophagy to inhibit the proliferation of colon epithelial cells or reduce hyperglycemia-induced matrix remodeling by glomerular endothelial cells via signaling pathways of AMP-activated protein kinase (AMPK) and mammalian target of rapamycin (mTOR) [112, 113]. In other conditions, exogenous H₂S can also suppress excessive activation of autophagy to protect against cigarette smoking-induced left ventricular systolic dysfunction [114] and alleviate traumatic brain injury or ischemia-reperfusion injury [115, 116]. Given the important role of autophagy in the pathogenesis of fibrosis and the regulatory function of H₂S for autophagy and fibrosis, it is reasonable and interesting to hypothesize that exogenous or endogenous H₂S might inhibit the development of fibrosis via targeting with autophagy or autophagy-associated signaling pathways.

(vi) The protective role of endogenous or exogenous H₂S in fibrosis pathogenesis is convincing from various animal models, but much remains unknown of its role in the pathogenesis of human fibrosis. Further clinical studies are needed to translate this potential to clinical use.

**Conflict of Interests**

The authors have declared no conflict of interests regarding the publication of this paper.

**Authors’ Contribution**

Shufang Zhang and Chuli Pan contributed to the acquisition and analysis of the data and the initial draft writing of
this paper. Feifei Zhou, Zhi Yuan, and Wei Cui contributed to the collection and interpretation of data. Huiying Wang contributed to the collection of the revised paper. Gensheng Zhang contributed to the concept of the review, the revision of this paper, and the final approval of the version to be published. Shufang Zhang and Chuli Pan contributed equally to this work.
