Background. To predict long-term treatment outcome of radiation therapy (RT) plus androgen deprivation therapy (ADT) for high-risk locally advanced prostate cancer. **Methods.** In total, 204 patients with the National Comprehensive Cancer Network (NCCN) high risk locally advanced prostate cancer (PSA > 20 ng/ml, Gleason score ≥ 8 , clinical T stage $\geq \text{T}3\text{a}$) were treated with definitive RT with ADT. Median follow up period was 113 months (IQR: 95–128). Median neoadjuvant ADT and total ADT duration were 7 months (IQR: 6–10) and 27 months (IQR: 14–38), respectively. **Results.** PSA recurrence-free survival (PSA-RFS), cancer specific survival (CSS), and overall survival (OS) rates at 5 years were 84.1%, 98.5%, and 93.6%, respectively, and 67.9%, 91.2%, and 78.1%, respectively, at 10 years. Pre-RT PSA less than 0.2 ng/ml was associated with superior outcomes of PSA-RFS (HR = 0.42, 95% CI: 0.25–0.70, $p = 0.001$), CSS (HR = 0.27, 95% CI: 0.09–0.82, $p = 0.013$), and OS (HR = 0.48, 95% CI: 0.26–0.91, $p = 0.021$). On multivariate analysis, age (≥ 70 y.o.) and pre-RT PSA (≥ 0.2 ng/ml) were factors predictive of poorer OS ($p = 0.032$), but iPSA, T stage, Gleason score, number of NCCN high-risk criteria, a combination with anti-androgen therapy and neoadjuvant ADT duration were not predictive of treatment outcome. **Conclusion.** In patient with high-risk prostate cancer, RT plus ADT achieved good oncologic outcomes. PSA < 0.2 ng/ml before radiation therapy is a strong independent predictor for long overall survival.

1. Introduction

In recent years, the National Comprehensive Cancer Network (NCCN) guidelines subdivided the risk classification of prostate cancer (PCa). According to the guidelines, radical prostatectomy or radiation therapy (RT) with androgen deprivation therapy is recommended for high-risk prostate cancer, initial PSA (iPSA) > 20 ng/ml, Gleason score ≥ 8 or locally advanced ($\geq \text{T}3\text{a}$). Additionally, RT should be performed in conjunction with 4–6 months of neoadjuvant ADT (NADT) and 2–3 years adjuvant ADT (AADT) in patients with high-risk PCa. The efficacy of NADT was reported in several phase III clinical trials, RTOG86-10 [1] and TROG9601 [2]. In addition, the results of EORTC22863

[3], RTOG85-31 [4], and RTOG92-02 [5] indicated that patients with high-risk PCa who received AADT had longer overall survival.

In combination with definitive local therapy, the role played by ADT is considered as follows; in NADT, the irradiation field can be narrowed in accordance with reduced tumor and prostate volume, leading to higher treatment efficacy and less adverse events [6]. Moreover, concurrent extra-beam radiation therapy (EBRT) with ADT can enhance apoptosis, and synergistic effect can be expected [7]. AADT can bring about a suppressing efficacy against residual tumor and micro-metastasis. In addition, early responses to ADT are thought to be associated with better prognosis in men with prostate cancer.

Emerging reports indicated the association between oncologic outcomes and biochemical response after NADT. In recent meta-analysis showed prognostic value of low PSA level before EBRT (pre-RT PSA) for localized PCa [8]. The importance pre-RT PSA level after NADT in patients with high-risk PCa has been demonstrated in several studies [9–12].

In the present study, we reported the long-term treatment outcome of EBRT plus ADT in patients with high-risk prostate cancer. Furthermore, we investigated the relationship between PSA value before EBRT and patient outcomes.

2. Materials and Methods

Between January 2005 and December 2010, a total of 216 patients with NCCN high risk (PSA > 20 ng/ml, Gleason score ≥ 8, clinical T stage ≥ T3a) localized prostate cancer were treated with definitive EBRT (70 Gy/35 fr) and ADT combination. We investigated the clinicopathological features and oncologic outcome retrospectively. Of 216 patients, 12 were excluded due to early dropouts or insufficient data sets. The study protocol was reviewed and approved by the institutional review boards of the participating institutions.

The patients' medical records were accessed through the hospital charts and/or electronic medical records. Data collection included demographic data, PSA level at diagnosis (iPSA), clinical T stage, pathological findings, treatment, tumor response parameters, and data on patient outcomes. Clinical T stage was evaluated using magnetic resonance imaging in all patients.

All patients received NADT using luteinizing-hormone-releasing hormone (LHRH) agonist alone or in combination

with the anti-androgens such as bicalutamide. Subsequently, they received definitive EBRT. Radiation therapy was delivered by 3-dimensional conformal radiation therapy (3DCRT) with 70 Gy. The clinical target volume included the prostate and seminal vesicles only and did not include regional pelvic nodes. Adjuvant ADT was continued for 24–36 months.

PSA levels after ADT and EBRT were principally obtained every 3 months the first 2 years and every 6 months thereafter. The lowest PSA before EBRT was defined as pre-RT PSA. Biochemical recurrence was defined as nadir PSA + 2.0 ng/ml based on the Phoenix definition [13]. Time to biochemical recurrence, time to cancer-specific death, and time to death were calculated from the start of ADT.

Table 1 shows patient and tumor characteristics. Median age was 71 y.o. (range: 57–83). The median initial PSA was 24.7 ng/ml (range: 1.9–282.5). The majority of the patients had clinical stage ≥ T3a (63.7%), and 64.2% of patients had Gleason score ≥ 8. 119 patients (58.3%) had more than 2 factors of NCCN high-risk category. Median follow up period was 113 months (IQR: 95–128). Median NADT period and total ADT duration were 7 months (IQR: 6–10) and 27 months (IQR: 14–38), respectively. 142 patients (69.9%) had anti-androgen therapy. Median pre-RT PSA was 0.20 ng/ml (range: 0.04–1.2).

PSA recurrence-free survival (PAS-RFS), cancer-specific survival (CSS), and overall survival (OS) were estimated using the Kaplan–Meier method and tested using the log-rank test. Prognostic factors for overall survival were explored employing univariate and multivariate analyses with Cox-proportional hazard model. All statistical tests were two-sided, and *p*-value < 0.05 was considered significant. All statistical analysis was performed using the SPSS version 25.0.

3. Results

Of the entire cohort, 17 and 42 men died from prostate cancer and other causes, respectively. The overall survival rates at 5 and 10 years were 93.6% and 78.1%, respectively. Prostate cancer-specific survival at 5 and 10 years were 98.5% and 91.2%, respectively, and PSA recurrence-free survival rate at 5 and 10 years were 84.1%, and 67.9%, respectively.

Number of NCCN high risk criteria = 1 (HR = 0.42, 95% CI: 0.24–0.74, $p = 0.003$), and pre-RT PSA ≤ 0.2 ng/ml (HR = 0.42, 95% CI: 0.25–0.70, $p = 0.021$) were significantly associated with better PSA progression free-survival. Significant variables in the univariate analysis and possible prognostic factors such as iPSA, Gleason score, and anti-androgen use were additionally studied in a multivariate Cox regression analysis; however, none of them was risk factor for PSA recurrence (Table 2).

Age ≤ 70 y.o. (HR = 0.50, 95% CI: 0.26–0.96, $p = 0.036$), T stage ≤ 2c (HR = 0.34, 95% CI: 0.15–0.77, $p = 0.009$), Number of NCCN high risk criteria = 1 (HR = 0.27, 95% CI: 0.12–0.61, $p = 0.002$), and pre-RT PSA ≤ 0.2 ng/ml (HR = 0.48, 95% CI: 0.26–0.91, $p = 0.024$) were associated with superior overall survival. Initial PSA ≤ 20 ng/ml, Gleason score ≤ 7, NAADT duration ≤ 6 months, and combination with anti-androgen were not relevant to overall survival. Significant variables in the univariate analysis were further studied in a multivariate cox regression analysis. Age ≤ 70 y.o. (HR = 0.51, 95% CI: 0.27–0.99, $p = 0.046$) and pre-RT PSA < 0.2 ng/ml (HR = 0.49, 95% CI: 0.26–0.94, $p = 0.032$) were independent variables associated with better OS (Table 3).

Comparisons of PSA-PFS, CSS, and OS rates according to pre-RT PSA levels are presented in Figures 1, 2, and 3,

respectively. Pre-RT PSA less than 0.2 ng/ml was significantly associated with better outcomes in PSA-PFS (HR = 0.42, 95% CI: 0.25–0.70, $p = 0.001$), CSS (HR = 0.27, 95% CI: 0.09–0.82, $p = 0.013$), and OS (HR = 0.48, 95% CI: 0.26–0.91, $p = 0.021$).

4. Discussion

Several clinical trials in the past years indicated the effectiveness of EBRT plus ADT for high risk localized prostate cancer. The results of RTOG86-10 and TROG9610 indicated the improvement of PSA progression-free survival, cancer-specific survival and overall survival in a patient treated with neoadjuvant ADT. Other randomized control studies (EORTC22863, RTOG85-31, RTOG92-02) regarding adjuvant ADT more than 2 years, showed significant longer overall survival in patient with locally advanced prostate cancer. In those studies, 5-years PSA-PFS and OS were 82.0–85.2%, 84.3–92.3%, 10-years PSA-PFS and OS were 58.4–71.4% and 67.0–80.2%, respectively. In our study, 5-years PSA-PFS, OS were 84.1%, 93.6%, and 10 years PSA-PFS and OS were 67.9% and 78.1%, respectively, which were comparable to the other reports.

In our institution, irradiation dose was determined by the radiologist 70 Gy/35 fr, and they do not perform dose escalation. Regarding dose of irradiation, the benefit of high dose irradiation of 74 Gy or more has been reported in recent years (PROG95-09 [15], MRC RT01 [16], MDACC [17]). Zelefsky et al. reported long recurrence free survival of high dose EBRT (dose escalation from 70.2 Gy to 89.4 Gy) in 2,551 patients with prostate cancer [18]. Furthermore, Nguyen et al. reported that significant better PSA-PFS and OS in the patients treated

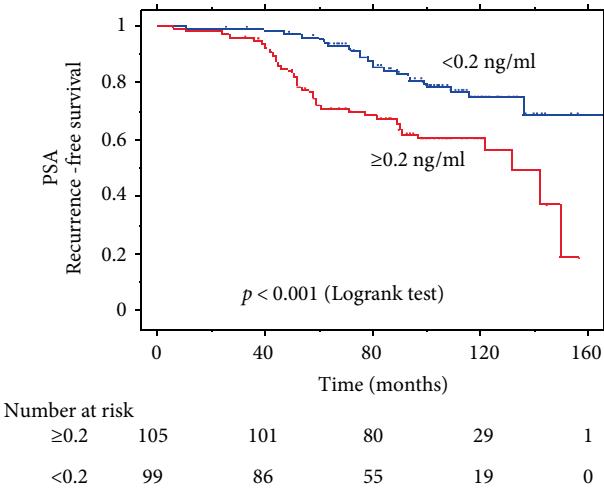

FIGURE 1: Kaplan–Meier survival curve of PSA-PFS by pre-RT PSA.

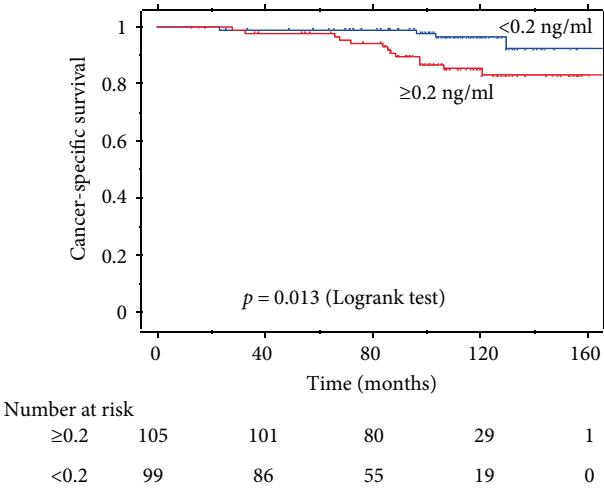

FIGURE 2: Kaplan–Meier survival curve of CSS by pre-RT PSA.

with high-doses EBRT of 75.6 Gy or more [19]. However, the high-dose irradiation seems to raise the frequency of severe adverse event related to genitourinary and gastrointestinal disorders [20, 21]. In addition, recent large RCT revealed dose escalation did not improve OS, despite improvements in PSA failure and distant metastasis [22]. In the present study, all 204 patients were treated with 70 Gy irradiation, and no patients had adverse events of grade 3 or more in the long follow-up period. From these results, it is considered that 70 Gy irradiation is tolerable for the patient with high-risk prostate cancer treated with ADT.

We assessed the relationship between clinicopathological factors and PSA recurrence, disease-specific death, and all-cause death. In univariate analysis, age, T stage, number of NCCN high-risk criteria, pre-RT PSA were prognostic factors. In multivariate analysis, age < 70 y.o. and pre-RT < 0.2 ng/ml were associated with significant good prognosis. Several reports showed that PSA before radiation therapy predicts good PSA recurrence-free survival, cancer-specific survival and overall

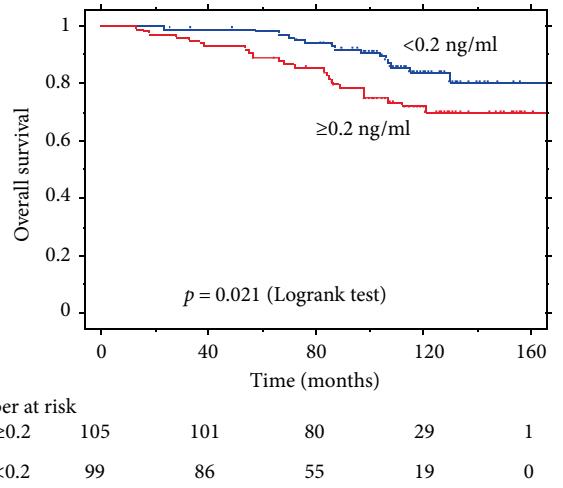

FIGURE 3: Kaplan–Meier survival curve of OS by pre-RT PSA.

survival. Zelefsky et al. conducted a retrospective analysis of the pre-RT PSA values in 1045 patients treated with ADT and EBRT. The 10-year PSA-RFS was 74.3% in good responders (pre-RT PSA < 0.3 ng/ml) compared to 57.7% in patients with higher PSA nadir values ($p < 0.001$) [9]. Alexander et al. also reported that pre-RT PSA < 0.1 ng/ml was associated better PSA-RFS, CSS, and OS in patients with localized prostate cancer and iPSA more than 40 ng/ml ($n = 64$) [10]. Additionally, Ludgate et al. analyzed 407 patients with NCCN high-risk prostate cancer and reported that patients with PSA nadir before irradiation less than 0.1 ng/ml had long cancer-specific survival [11]. Pre-RT PSA value during NADT may be an indicator to determine local disease control and suppression of micro-metastasis. Therefore, lower pre-RT PSA can predict favorable prognosis in patients with high risk localized prostate cancer.

However, there is no evidence that oncologic outcome can be improved by the prolongation of NADT or combined androgen blockade with anti-androgens before irradiation. In the present study, the duration of NADT was not associated with better prognosis. The above-mentioned study by Ludgate et al. reported that the duration of the NADT and total ADT were not associated with better PSA-RFS, CSS, or OS [11]. In our data, also, the duration of NADT was not associated with better prognosis in multivariate analysis. Furthermore, patients achieved lower pre-RT PSA were more likely to be treated with anti-androgens, however, combined androgen blockade was not associated with superior outcome. Thus, intensive treatment to reduce PSA value may not have high efficacy in the cancer control before irradiation. Overall survival of patients showed slow PSA response cannot be improved by unnecessarily long-term NADT or the addition of anti-androgen.

Therefore, PSA response to primary NADT is an indicator for determining whether a more powerful treatment should be selected. In other words, patients who could not achieve abovementioned minimum PSA levels after NADT should be followed up carefully, and advanced treatment may be considered for them.

Recently, many reports have shown effectiveness of tri-modality therapy using brachytherapy, EBRT, and ADT in combination for patients with high-risk prostate cancer [23, 24]. Furthermore, ASCEND-RT trial data showed that, low-dose-rate brachytherapy boost with whole pelvic irradiation has superior potential compared with dose escalated EBRT in patients with intermediate- and high-risk prostate patients [25]. Induction of the curative modalities possibly improve the prognosis of patients whose pre-RT PSA high before irradiation. Predicting endogenous radiosensitivity early after the initiation of ADT may enable individualized treatment in selected prostate cancer patients at high risk. Accordingly, significant decline of PSA with neoadjuvant ADT is an important indicator for selecting more intensive therapy for patient with high risk localized prostate cancer.

In the interpretation of the current study's results, there are several limitations. First, this study is a single center retrospective cohort, therefore, it includes a relatively small sample size and the biases in patient and treatment selection. Second, total RT doses used in modern practice are generally higher than those used during the era of this study from 2005 to 2010. Therefore, it is controversial whether it can adapt to the current standard RT and dose escalated RT.

5. Conclusion

In conclusion, achieving pre-RT PSA < 0.2 ng/ml, rather than patient characteristics, was significantly associated with superior PSA recurrence-free survival, cancer-specific survival, and overall survival in patients with high-risk locally advanced prostate cancer treated with ADT and RT. If the pre-RT PSA does not reach low levels, combination therapy with more powerful modality such as brachytherapy could improve treatment outcome.
