Innovative approaches to neuraxial blockade in children: The introduction of epidural nerve root stimulation and ultrasound guidance for epidural catheter placement

Ban CH Tsui MSc MD FRCPC

BCH Tsui. Innovative approaches to neuraxial blockade in children: The introduction of epidural nerve root stimulation and ultrasound guidance for epidural catheter placement. *Pain Res Manage* 2006;11(3):173-180.

Continuous epidural blockade remains the cornerstone of pediatric regional anesthesia. However, the risk of catastrophic trauma to the spinal cord when inserting direct thoracic and high lumbar epidural needles in anesthetized or heavily sedated pediatric patients is a concern. To reduce this risk, research has focused on low lumbar or caudal blocks (ie, avoiding the spinal cord) and threading catheters from distal puncture sites in a cephalad direction. However, with conventional epidural techniques, including loss-of-resistance for localization of the needle, optimal catheter tip placement is difficult to assess because considerable distances are required during threading. Novel approaches include electrical epidural stimulation for physiological confirmation and segmental localization of epidural catheters, and ultrasound guidance for assessing related neuroanatomy and real-time observation of the needle puncture and, potentially, catheter advancement. The present article provides a brief and focused review of these two advances, and outlines recent clinical experiences relevant to pediatric epidural anesthesia.

Key Words: *Electrical epidural stimulation; Epidural anesthesia and analgesia; Pediatric; Review; Ultrasound*

Precise identification of the needle and catheter in the epidural space is critical for effective and safe continuous epidural anesthesia. Particularly for pediatric patients, accurate segmental localization is important for avoiding local anesthetic toxicity and side effects through maximizing effect with minimal doses. Single-shot epidural blocks are associated with limited duration and segmental effects, and continuous epidural anesthesia has become popular to overcome these limitations (1). The standard for epidural needle localization technique has been loss-of-resistance (LOR) to saline or air, which has fairly accurate results for needle placement and remains popular (2). The challenges for accurately threading catheters within the small pediatric epidural space without malpositioning, while also confirming safe catheter tip placement at target nerve root levels, has spurred interest and research in guidance and localization techniques.

In the pediatric population, the introduction of both the stimulation catheter and ultrasound guidance for use in epidural

Des modes novateurs de bloc neuraxial chez les enfants : Présentation de la stimulation de la racine nerveuse péridurale et orientation échographique pour l'installation d'un cathéter périurale

L'anesthésie périurale continue demeure la pierre angulaire de l'anesthésie régionale pédiatrique. Cependant, le risque de traumatisme catastrophique de la moelle épinière pendant l'insertion directe d'aiguilles dans les zones thoracique et lombaire haute chez les patients pédiatriques anesthésiés et ayant reçu de puissantes doses sédatives est inquiétant. Pour réduire ce risque, les recherches ont porté sur les anesthésies lombaires basses ou caudales (qui évitent la moelle épinière) et l'introduction d'un cathéter dans des foyers de perforation distale vers la tête. Cependant, avec les techniques périurales traditionnelles, y compris la perte de résistance pour localiser l'aiguille, il est difficile d'évaluer l'installation optimale du bout du cathéter à cause de l'importante distance d'insertion. Les modes novateurs incluent la stimulation périurale électrique pour la confirmation physiologique et la localisation segmentaire des cathéters périurales et l'orientation échographique pour évaluer la neuroanatomie connexe et l'observation en temps réel de la perforation à l'aiguille et peut-être, la progression du cathéter. Le présent article fournit une brève analyse ciblée de ces deux progrès et souligne les récentes expériences cliniques de l'anesthésie périurale en pédiatrie.

anesthesia has received attention over the past several years. The technique of using electrical stimulation for accurate epidural catheter placement (also known as the Tsui test) has been described as "an important innovation" with predictions that this technique "should improve the safety of [epidural anesthesia]" (3). An editorial in *Regional Anesthesia and Pain Medicine* expanded on this with, "the Tsui test is easy to perfect and is probably one of the better determinants of catheter tip placement without any extra radiographic examinations...we are at the brink of a new era for improving the accurate placement of regional anesthesia catheters in anesthetized children" (4). The 'new era' described in this editorial suggests that epidural stimulation has the potential to resolve some of the key concerns in pediatric epidural anesthesia. Recently, in addition to the epidural stimulation test, epidural placement under ultrasound guidance has been introduced and shown to be beneficial in some pediatric studies (5-7). To overcome certain challenges associated with performing epidural anesthesia

in children, including the anatomical space and requirement for deep sedation or anesthesia (with lack of sensory warnings from the patient), real-time visualization of the epidural space is promising. Ultrasound is particularly promising for the neonate and infant population (particularly for infants younger than six months of age) because their epidural spaces are more superficial and bony structures less developed than in adults (5). Nevertheless, one recent review article (2) summarized the current status of using ultrasound for epidural placement as "ultrasonography can be used to identify neuraxial structures during insertion and placement of epidural catheters in children," and "this technique is not meant to become routine practice for localization of the epidural space as it requires a rather complicated and expensive setting to guarantee sterility" (2).

The present article provides a brief and focused review on the new concepts of electrical stimulation and ultrasound to confirm and guide epidural catheter positioning, and outlines recent clinical experiences with these important advancements in pediatric epidural anesthesia.

ISSUES IN PEDIATRIC EPIDURAL ANALGESIA

Epidural anesthesia and analgesia have many beneficial effects in the pediatric patient population. Central neuraxial block not only improves postoperative pain relief, but also promotes earlier ambulation, allows rapid weaning from the ventilator, reduces time spent in the catabolic state and lowers circulating stress hormones (8). The key to effective epidural analgesia is accurate placement of the epidural catheter.

Precise placement of epidural catheters ensures that the dermatomes involved in the surgical procedure are selectively blocked, allowing minimal doses of local anesthetics to be used for maximal analgesia (9-11). Despite the many benefits of epidural analgesia, there is always an associated risk of catastrophic needle trauma to the spinal cord from direct thoracic and high lumbar epidural needle placement. The risk of such an event may be elevated in children because their epidural spaces are considerably smaller than those of adults (less than 2 mm in small babies) (7,12), and epidural catheter placement is commonly performed under sedation or general anesthesia. Although reports of perioperative nerve injuries in pediatric patients receiving epidural anesthesia are rare, the fact that unconscious patients are unable to report paresthesias (the currently accepted warning sign of needle encroachment on the spinal cord) raises concern (13-18). Failure to recognize epidural needle or catheter placement in the intrathecal space followed by the injection of the usual epidural dose could also result in a total spinal block or serious neurological sequelae (19-22). The thoracic epidural space is particularly challenging in children because the spinal canal is narrower and catheter threading more challenging.

To circumvent the risks and technical challenges associated with thoracic or high lumbar needle punctures, threading epidural catheters from puncture sites at the low lumbar or caudal space (at the sacral notch) was introduced, although with variable success (23-26). Intuitively, shifting the puncture site caudally should be an attractive and feasible alternative to direct placement for procedures and major surgery involving dermatomes above T10 (27). However, the possibility of the catheter coiling and failing to advance to the appropriate level discouraged the widespread use of these approaches. Subsequently, it became well understood that the location of

the catheter tip must be verified using an objective test such as radiography (28), ultrasound (29) or nerve stimulation (30). In addition, controlling catheter positioning is important for longer distances of insertion because there will be a greater danger of unwanted migration (2).

X-ray imaging, in conjunction with a contrasting agent or radiopaque catheter, can precisely identify the tip of the catheter in specific anatomic locations. However, while fluoroscopy permits continuous real-time monitoring and adjustment of advancing catheters, it requires additional set-up, incurs increased expense and, more importantly, increases the patient's exposure to ionizing radiation (1). As a result, fluoroscopy is commonly avoided for routine use and is usually limited to difficult and/or special circumstances such as chronic epidural catheter placement. The electrical stimulation test, and to some extent ultrasound, has been shown to be more promising for catheter tip confirmation.

ELECTRICAL STIMULATION TEST

Basic concepts

The original epidural electrical stimulation test (Table 1) described by Tsui et al (30) confirms epidural catheter placement through stimulation of the spinal nerve roots (not the spinal cord) with low electrical current conducted through normal saline in the epidural space via an electrically conducting catheter. The stimulating catheter set-up requires the cathode lead of the nerve stimulator to be connected to the epidural catheter via an electrode adapter, while the anode lead is connected to an electrode on the patient's skin as the grounding site. To avoid misinterpretation of the stimulation response (eg, local muscle contraction may be confused with epidural stimulation), the ground electrode should be placed on the lower extremity for thoracic epidurals and on the upper extremity for lumbar epidurals. Because the typical epidural catheter is positioned 1 cm to 2 cm from the nerve roots, correct placement is indicated by a motor response elicited with a current between 1 mA and 10 mA (30-32). Any motor response observed with a significantly lower threshold current (less than 1 mA) may indicate that a catheter is in the subarachnoid or subdural space, or is in close proximity to a nerve root (33,34). In these rare cases, a motor response is elicited with a significantly lower threshold current because the stimulating catheter is either very close (less than 1 cm) to the nerve roots or in direct contact with highly conductive cerebrospinal fluid.

In addition to confirming final catheter positioning, the epidural stimulation test can allow dynamic control over catheter placement, thereby assisting smooth placement and adjustments in the event of catheter migration, kinking or coiling. Elicited muscle twitches are observed from the lower limbs to the intercostal muscles as the catheter is threaded cranially. This minimizes the concerns of catheter coiling or kinking by immediately identifying these events at the time of insertion, allowing for any necessary adjustments (35,36). The absence of muscle twitches or resistance to the advancing epidural catheter may be indicative of a curled or kinked catheter.

Equipment

There are two main requirements to effectively guide stimulating epidural catheters, particularly when long threading distances are required. The catheter set-up must be amendable to

TABLE 1
Epidural electrical stimulation test (Tsui test)

Catheter location	Motor response	Current
Subcutaneous	None	NA
Subdural	Bilateral (many segments)	<1 mA
Subarachnoid	Unilateral or bilateral	<1 mA
Epidural space	Unilateral	<1 mA
against nerve root		
Nonintra-vascular	Unilateral or bilateral	1 mA to 10 mA (threshold current increases after local anesthetic is injected)
Intra-vascular	Unilateral or bilateral	1 mA to 10 mA (no change in threshold current after local anesthetic is injected)

Confirmation of catheter placement in the epidural space is received once obtaining either a bi- or unilateral motor response, and when the threshold current is 1 mA to 10 mA initially and increases with injection of local anesthetic

both conducting electricity and preventing catheter malpositioning from coiling and kinking. Metal-containing catheters and conducting solutions are necessary for electrical conductivity, while adding reasonable rigidity through metal stylet reinforcement will assist correct positioning. Currently, neither commercially available peripheral stimulation catheters nor regular epidural catheters meet these requirements sufficiently, and modifications have been described which enable proper set-up. Thus, a special, commercially manufactured styletted catheter set-up (Epidural Positioning System using Tsui test with FlexTip Plus catheter, Arrow International Inc, USA) was previously developed (Figure 1) to achieve the requirements.

To conduct electrical pulses for eliciting appropriate motor responses, the peripheral stimulation catheter (eg, Stimulong Plus, Dyna Medical Corp, Canada; Pajunk GmbH Medical Technology, Germany) incorporates an internal fixed wire that extends beyond the distal lumen tip. Conversely, regular soft metal-containing epidural catheters (eg, FlexTip, Arrow International Inc, USA; Perifix FX, B Braun Medical Inc, USA; Spirol, Smith's Medical, USA), do not have their metal tip ending past the catheter and therefore require the injection of a conducting fluid into the epidural space to elicit a motor response. An ionic solution such as normal saline is used as the priming solution for the catheter. Despite this solution, the metal coil in the lumen (in contact with the conducting solution) is still required because the long length of the epidural catheter, or any air lock within its lumen, can increase the resistance for current flow and impede the electrical conduction through the solution. Based on the above requirements, the Arrow FlexTip Plus catheter was used in the initial clinical work (30-32). This catheter is an open-tip, single-orifice catheter constructed of a circumferential stainless steel coil with soft polyurethane. Regardless of manufacturer, previously mentioned metal-containing catheters are all suitable for performing the epidural stimulation test (37). Stimulating peripheral catheters have also been used successfully when performing the epidural stimulation test (38).

Figure 1 Equipment set-up (Epidural Positioning System using Tsui test, Arrow International Inc, USA). The set-up includes a commercially available 20-gauge epidural catheter with stylet and Johans electrocardiograph adapter assembly. The catheter assembly is passed through an 18-gauge intravenous catheter and the negative lead of the nerve stimulator is connected to the metal hub of the electrocardiograph adapter

While electrical conduction characteristics are paramount for indicating potential catheter migration or coiling, and confirming final catheter position, the regular metal-containing catheters are too soft for threading catheters over substantial distances, as with pediatric patients. To circumvent this, catheter reinforcement with a metal stylet to add some stiffness is desirable. While this stylet will increase ease of advancement within the epidural space, the electrical conduction characteristics need to be maintained; therefore, further modification to allow saline injection from the stylet-reinforced catheters is important.

Another function of this saline injection is to lubricate the epidural space to smooth the passage of the catheter. The fluid may reduce friction between the catheter and surrounding neural and connective tissue and, thus, limit encounters disrupting its advancement. Minor resistance to the passage of the catheter can be overcome by injecting normal saline through the advancing epidural catheter and/or simple flexion, or extension of the patient's vertebral column (36). Recently, the use of multiport catheters has been introduced and shows promise to maximize this lubrication effect (39). However, clinicians must remain vigilant because all techniques of epidural catheter placement have the potential for neurological injury. Therefore, under no circumstances should any force be used to advance the catheter.

Using the described design features, including a stylet and injection port system, epidural catheters have been successfully threaded from the caudal to thoracic spaces. In Canada, positive results have been demonstrated using a manufactured special styletted catheter set-up (Figure 1) (Arrow International Inc, USA) (39). However, in countries where those kits are not available, similar results can be obtained by 'in-house' modification of regular metal-containing catheters (39,40). Despite this, widespread clinical use of epidural stimulation testing will obviously depend on further production and distribution of systems with the necessary features.

The safety of epidural electrical stimulation

Electrical stimulation has been applied to neural structures for neurophysiological evaluation or pain control for decades (41). Chronic spinal cord stimulation has been shown to be an effective and safe means of controlling pain (41-44). The certainty of the safety of epidural stimulation is not completely known. However, it is anticipated that the risk of a brief intermittent electrical stimulation used in this test would be even lower than that of chronic epidural stimulation used in long-term pain management. Epidural stimulation uses milliamperage currents within the range used for patients with chronic pain disorders (4 mA to 30 mA) (45) and for intraoperative monitoring during spinal surgery (2 mA to 40 mA) (42,46-49). Although no known complications or patient discomfort have resulted from the epidural stimulation test, keeping the current below 15 mA and the stimulation time as brief (few minutes) as possible is recommended (30-32,35,36). In particular, the current output must be carefully increased from zero and stopped once motor activity is visible to ensure that all motor responses, even those elicited with low current (less than 1 mA), are detected. In addition, the nerve stimulator must be sensitive to allow a gradual increase in current output but should also be able to deliver currents to at least 10 mA.

Clinical applications

Detecting intrathecal and intravascular placement:

Aspiration should always be performed before local anesthetic injection. However, the inability to aspirate blood or cerebrospinal fluid is not an absolute indication that an epidural needle or catheter is not in the intrathecal or intravascular space. The use of electrical stimulation for epidural anesthesia may not only be useful to confirm epidural catheter placement, but the threshold current for motor response may also predict intrathecal placement (33,38,50,51). When a catheter is situated properly within the epidural space, a current much greater than 1 mA should be required to elicit muscle twitches (30,31,52). However, if any motor response is detected with a current less than 1 mA, intrathecal placement should be suspected. Two recent clinical studies (51,53) in pediatric patients demonstrated that the mean current necessary to elicit a motor response with insulated needles in the epidural space (3.84 ± 0.99 mA and 5.2 ± 2.4 mA, respectively) is much higher than that in the intrathecal space (0.77 ± 0.32 mA and 0.6 ± 0.3 mA, respectively). The advantage of this real-time stimulation test is that intrathecal placement can be ruled out before the administration of a potentially harmful test dose.

A previous obstetric study (31) has shown that repeated injections of local anesthetic into a properly placed epidural catheter results in impairment of nerve conduction, and requires a gradual increase in the amplitude of electrical current to produce a positive motor response to the stimulation test. Absence of this trend after repeated doses of local anesthetic suggests that the injected local anesthetic may be rapidly disappearing from the epidural space, as is the case with intravascular placement. Thus, intravascular catheter placement may be indicated by a positive motor response to appropriate stimulation currents (1 mA to 10 mA) that remain at or return to the baseline levels (ie, before any local anesthetic injection) despite the administration of local anesthetics. In addition to the obstetric study, intravascular catheter placement was detected using epidural stimulation in another case report (33). Caution is required when extrapolating this information

because this application has never been examined in the pediatric population. An adrenaline test dose ($0.5 \mu\text{g/kg}$) should still be administered to identify inadvertent intravascular placement via specific electrocardiograph (ECG) changes (ie, greater than 25% increase in T wave or ST segment changes irrespective of chosen lead) (54,55). Tobias (55) recommends the use of adrenaline test doses in children, because in all the studies he reviewed the specificity of the ECG changes was 100%. Therefore, the ECG should be continuously monitored while injecting a local anesthetic and adrenaline test dose into the epidural space. However, when combined with the epidural stimulation test, the test dose can be given with confidence of a reduced risk of causing total spinal block.

Guiding epidural placement:

Caudal approach: Bosenberg et al (24) first described the technique of advancing catheters from the caudal space to the lumbar and thoracic region in infants and children. Subsequent studies have recommended that caudal catheter anesthesia should be limited to patients younger than one year of age because development of the lumbar curve during infancy can prevent easy threading of the catheter and may cause catheter kinking (28). However, with the introduction of new equipment and techniques, recent reports have demonstrated that caudal catheter advancement is even possible in older children using epidural stimulation (4,36,40). The improved success rate in older children has been attributed to the use of a styletted catheter, which also allows the simultaneous injection of saline during advancement, and perhaps more importantly, the ability to monitor the advancing catheter tip by stimulation (36).

Before the introduction of the epidural stimulation test to confirm catheter placement at the author's institution, the analgesic success rate from pediatric epidural catheter placement was unacceptably low (68%) (35). It is likely that improper catheter placement may have been a major contributing factor to this because during this time period confirmation techniques were thought to be impractical and as a result were rarely used (25,27). However, following the introduction of the epidural stimulation test, the success rate of caudal analgesia increased dramatically to 84.9%, while side effects remained at a minimum (36). By precisely placing epidural catheters close to the appropriate dermatomes with the help of epidural stimulation, the surgical incision may be selectively blocked with low doses of medication (10,11,56). Consequently, surgical stress for the patient is reduced, along with any potential side effects. This is particularly important for neonates and infants, because they are prone to profound oxygen desaturation when distressed.

Effective analgesia without sedation, such as that provided by epidural anesthesia, can reduce the risk of prolonged postoperative ventilation. With properly sited epidurals, an infusion of 0.1% bupivacaine with $1 \mu\text{g/mL}$ of fentanyl is safe and effective in neonates and children (36). It is important to note that fentanyl is highly lipid soluble, with limited spread within the epidural space. This results in effective analgesia only when the epidural catheter tip is placed precisely at the incision level. From the author's experience, this advance to caudal catheter placement has obviated the need for ventilatory support in many children following major thoracic and abdominal procedures. Similar outcomes have also been reported in other centres using the same technique (40).

Increased risk of infection is a concern when using the caudal approach because the puncture site of the needle is in close

proximity to the anus. However, clinical evidence to indicate a higher rate of infection with the caudal approach as opposed to a lumbar or thoracic approach has not been found despite higher bacterial colonization on caudal catheters (36,57). Tunnelling caudal catheters or simply fixing the catheter with sterile occlusive dressing in an immediate cephalad direction has been recommended to reduce the risk of contamination by stool and urine (36,58).

Lumbar approach: Lumbar epidural anesthesia is often used in lower extremity and urological surgery. Previous reports (23) of attempts to thread lumbar epidural catheters to the thoracic segment without epidural stimulation have described lack of success, because the flexible catheter tip is met with undue resistance at the lumbar curve. Despite favourable results using stimulation via a caudal approach, there have been only two recent case reports (39,59) demonstrating the successful placement of a thoracic epidural catheter via the lumbar route with epidural stimulation guidance. Obviously, with so few cases of thoracic epidural catheter placement via lumbar approach using nerve stimulation, caution is required before making generalizations about the merits of this technique for this approach. Further research and study is warranted.

Thoracic approach: When using a direct thoracic approach, one is not limited by the ability to thread the epidural catheter because the selected site of entry corresponds directly with the dermatomes involved in the surgery. In this situation, epidural catheter stimulation does not seem to have significant benefit to LOR for improving accurate epidural catheter placement at specific nerve root levels (60). As previously mentioned, inadvertent intrathecal or intraneural needle placement may possibly be identified by patient reports of paresthesia or pain upon injection. Because pediatric patients are deeply sedated or under general anesthesia during placement of the neuraxial block, the electrical stimulation test may be an additional safety measure to alert the clinician of needle proximity to the intrathecal space, spinal cord or nerve root (50,61). Thus, while it may not be advantageous for catheter placement verification with these blocks, electrical stimulation may still be useful.

Limitations of epidural stimulation

A major limitation of the epidural stimulation technique is that this test must be performed in the absence of a significant clinical neuromuscular blockade or local anesthetics in the epidural space. Although these obstacles can be overcome in many circumstances, alternative methods will be desirable in some cases. Tsui et al (62,63) developed one such alternative monitoring technique using ECG monitoring. Essentially, the amplitude of the QRS complex matches the surface electrode amplitude as it passes the target level. A study (62) has shown that this technique can guide the catheter tip within two vertebral spaces of the targeted level. However, unlike the epidural stimulation test, the ECG technique cannot warn of a catheter placed in the subarachnoid or intravascular space. In addition, if the catheter is only threaded a short distance, the precise level of catheter may be difficult to predict because a significant difference in ECG signals would be difficult to detect. Recently, ultrasound imaging has been introduced and would be an alternative method for young children, although it is limited at this time for older children and adults (see next section).

Minor limitations of electrical stimulation are the need and cost for a 'specialized' stimulating catheter. However, the cost

of the catheters may not be significant; clearly, the cost of ineffective analgesia or intrathecal/intervascular placement would be much higher. Because this epidural stimulation test can be performed in conscious patients without discomfort, satisfaction with the technique has been consistently high for both pediatric and adult patients in the author's experience.

ULTRASOUND GUIDANCE FOR CAUDAL OR EPIDURAL CATHETER PLACEMENT

Basic concepts

Ultrasound guidance during regional anesthesia is a rapidly growing interest for many anesthesiologists. The echotexture of the nerves and their surrounding structures is visualized through reflection of the ultrasound waves. In the periphery, nerves can be distinguished from surrounding soft and connective tissues by their shape, size and echogenicity. Nearby bony structures, being highly hyperechoic, and blood vessels, especially with Doppler assistance, are often used for verification of the nerve identity.

Ultrasound imaging can be an excellent tool to identify neuraxial structures in infants and children, particularly as their epidural spaces are superficial and the posterior elements of the spinal canal are less ossified than those of adults (5). The issue with extensive ossification in those much older than six months of age is that most of the ultrasound beam is reflected upon contact with the spinous processes and related bony structures. Visualization of the dura mater is thought best (6), although the ligamentum flavum, intrathecal space, spinal cord, nerve roots and fibres can all be seen adequately via a soft tissue window among the bony structures (7). Thus, continuous visualization of needle tip penetration and catheter advancement is often difficult. Indeed, precise catheter tip identity has been suggested to only be possible in infants younger than one year (64) or six months (29) of age, without the use of metal-coiled catheters (65). With ultrasound, the needle is often identified by the tissue it displaces and by an acoustic shadow beyond its tip (12). Catheter advancement is generally visualized indirectly by the surrogate markers of spread of injectate and movement of dura in the vicinity of its tip.

Equipment

Initial use of ultrasound in regional anesthesia by La Grange et al in 1978 (66) included Doppler ultrasound blood flow detection and vascular identification to estimate the position of nearby nerves. Today, technological developments have allowed ultrasound systems to deliver high-frequency sound waves (10 Hz or higher), offering the high resolution required for visualization of nerves and other tiny anatomical structures (12). While Doppler is still valuable to illuminate vascular landmarks when searching for nerves, it is no longer the primary approach in regional anesthesia. Although high-resolution images are possible in many circumstances, the depth of penetration varies inversely with the resolution, and there is often a tradeoff between depth and clarity of the image (5). This is especially relevant to viewing the epidural space, where deeper structures may be best viewed at lower frequencies with corresponding less clarity. As stated previously, children's epidural spaces are more superficial than those of adults, lending to somewhat higher resolution imaging (5 MHz to 10 MHz) (6).

Beyond delivery of the needed resolution, the portability and reduced cost of the machines make the technique viable in

a clinical operating room setting. Available ultrasound systems are equipped with complex software to provide good visualization of tissue contrast at both superficial and deep levels, as well as allow image and data file storage (5). Several companies manufacture portable machines, including Sonosite Inc (USA), Toshiba (USA) and General Electric (USA).

Clinical applications

Potential advantages of using ultrasound compared with conventional techniques in regional anesthesia relate to the direct visualization of nerves, related anatomical structures and local anesthetic spread. This visualization may facilitate direction, for realignment of the needles for optimal local anesthetic spread; avoidance of intraneural and intravascular injections; reduction in dose of local anesthetic; faster sensory onset time; and longer duration and quality of blocks (5). Beyond puncture practices and application of medication, ultrasound may provide the anesthesiologist with a clear picture of the anatomical situation before administering the block (67). Ultrasound has been proven beneficial during peripheral nerve blocks in adults and children, with advantages over nerve stimulation (68,69) and landmark-based techniques (70-72). Despite these benefits, evidence that ultrasound is widely acceptable and useful for central neuraxial block in children is still limited. A few studies have focused on the visibility of the needle and catheter, because the spinal canal is typically difficult to visualize sonographically (particularly in adults). Few others have studied the clinical efficacy of such use.

Chawathe et al (29) recently reported that, due to calcification of the posterior vertebral bodies in older children, ultrasound imaging is only reliable when used to image epidural catheters in children younger than six months of age. This imaging was performed after the block procedure rather than during insertion. Another study (64) concluded that one month of age was the threshold for clear catheter tip visibility, although only three children were studied (one, eight and 10 months of age). These studies used catheters without much echogenic property; the use of metal-coiled catheters, which appear bright with striated features, may circumvent this deficiency (65).

Measurements of the relationship between reference structures is a primary benefit of ultrasound; for example, the distance between the skin and epidural space can be measured before the epidural procedure, and the length of needle penetration when using the LOR technique can be estimated. Rapp et al (7) studied ultrasound-guided lumbar epidural catheter placement in 23 children and found a good correlation ($r=0.88$) of ultrasound-measured depth of the epidural space with that from LOR (7). These authors reported fairly good visualization of the catheters, although only during insertion and therefore without ability to reassess the position postprocedure.

Comparing catheter placement using ultrasound guidance with that of LOR, Willschke et al (6) concluded that ultrasound, through visualizing the local anesthetic spread and neuraxial structures, speeded execution and reduced bone contacts during lumbar and thoracic epidural catheter placement in 64 children. Whether these primary outcome measures are appropriate or substantial enough to promote ultrasound guidance during pediatric epidural procedures is somewhat questionable. During LOR attainment, bone contact is often sought to confirm that the needle is 'walked off' the bone and

hence, judging ultrasound as superior with reduced contact is perhaps misleading. The fact that these authors still found 17% bone contacts can also indicate poor visualization, because clear imaging should reduce this significantly. The bone was obviously misinterpreted as soft tissue; this highlights the fact that visualization of needle tips and tissue under ultrasound guidance is subject to significant operator interpretation. In addition, the authors did not include ultrasound start-up and preparation time with their calculation of swiftness, and the catheters were only threaded 2 cm to 3 cm. Despite these, there was good ability to measure the skin-to-epidural space and epidural diameter.

It is likely that many more reports of studies will be published in the near future to help assess the merit of ultrasound for pediatric neuraxial techniques. Likely, the main benefits will be preprocedure estimation of the epidural depth and diameter, as well as diagnosing variations in difficult conditions, such as scoliosis. Dynamic imaging and adjustment of catheters during threading may be helpful, especially with metal-coiled catheters. Visualizing the spread of local anesthetic should help reduce the dose of local anesthetic needed for maximum therapeutic effect. Improving safety and quality of blocks is still largely unknown at this time. Clearly, a cost-benefit analysis needs to be performed at each institution until more is known.

Limitations of ultrasound

Ultrasound imaging for regional anesthesia takes considerable time and effort to learn. Attempts to reduce the long learning curve may be effective to promote this technology throughout the anesthesiology community. Methods to best align the transducer with the block needle, to optimally view the needle tip and shaft, are continually sought (73). An important concern with continuous nerve blockade is the requirement for an assistant to hold the ultrasound probe during catheter advancement, making resource allocation an obvious consideration. The expense for the equipment, primary and additional practitioner training, as well as specific supplies and environment required for ultrasound (strict sterility is essential), may limit the benefit (2). These resources would, in the event of increased efficacy and safety, be justified.

Whether ultrasound guidance during epidural anesthesia improves safety, especially over that of epidural electrical stimulation, has yet to be determined. Understandably, it is hard to assess safety in situations of very rare incidence of harm. Regardless, the ability of electrical stimulation to confirm entrance to the epidural space and warn of intrathecal placement, both without a considerable learning curve, may promote this technique over that of ultrasound – at least with current technology and knowledge. However, with rapidly advancing technology, the image quality and capabilities of ultrasound will certainly improve and shorten the learning curve, making ultrasound more favourable. Nevertheless, time and study will tell.

SUMMARY

Epidural anesthesia can provide safe and effective analgesia in children. However, one must consider which epidural approach will be superior and which confirmation technique, if needed, will assist optimal catheter placement. Regional anesthesia techniques are intended for analgesia, rather than anesthesia, and very few adverse events should therefore ensue

(2). Major complications from epidural anesthesia are rare if proper technique and precaution is exercised. Perhaps now, with the introduction of the stimulation catheter and portable ultrasound machines, anesthesiologists may have reliable tools not only to confirm catheter placement in the epidural space, but also to accurately determine where the catheter tip is in the central neuraxis. Apart from improving efficacy and safety, these techniques will also be valuable for training purposes (1). Although there has been a great deal of progress in the development of epidural techniques, there is still no evidence that direct thoracic epidural placement can be performed without risk. Thus, the risks and benefits of epidural blockade must be considered on an individual basis (74).

ACKNOWLEDGEMENTS: Supported in part by a Clinical Investigatorship Award, Alberta Heritage Foundation for Medical Research, Alberta. The author had a previous patent license agreement (US patent #6190370) with Arrow International Inc (USA) for the epidural kit described in the present article.
