H Shuchang, H Mingwei, J Hongxiao, et al. Emotional and neurobehavioural status in chronic pain patients. *Pain Res Manage* 2011;16(1):41-43.

OBJECTIVE: To investigate the emotional and neurobehavioural status of patients suffering from chronic pain.

METHODS: Fifteen male patients with chronic lower back pain and 15 healthy control subjects were studied for approximately six months. Pain was measured using a visual analogue scale. The WHO Neurobehavioral Core Test Battery (NCTB) was used to assess neurobehavioural effects of environmental and occupational exposures.

RESULTS: Visual analogue scale results demonstrated a modest range of reported pain (mean $\pm$ SD) 62.0 ± 10.8 in chronic pain patients, whereas control subjects reported no measurable pain. With the NCTB, it was found that scores of negative mood state, including anger-hostility, depression-dejection, fatigue-inertia and tension-anxiety in pain patients were significantly higher than scores in the control subjects. By contrast, scores of positive mood state (vigour-activity) in chronic pain patients were lower than those in the control group. The NCTB scores of the Santa Ana Dexterity and Pursuit Aiming II tests in chronic lower back pain patients were lower than those of the control group. Scores for other NCTB subtests, including the Digit Span, Benton Visual Retention and Digit Symbol tests, were not significantly different compared with controls.

CONCLUSIONS: Chronic lower back pain patients had more negative mood and less positive mood than controls. These patients also demonstrated neuromotor deficits in coordination and reaction time. Further studies are required to examine possible neurological mechanisms and research potential intervention strategies for patients suffering from chronic pain.

Key Words: *Chronic pain; Mood state; NCTB; Neurobehavioural*

Chronic pain can be defined as "pain that has lasted 6 months or longer, is ongoing, is due to non-life threatening causes...and may continue for the remainder of the patient's life" (1). Pain is common in clinical populations and is often underestimated and undertreated. Prevalence rates vary considerably depending on research definitions used, the population sampled and other factors, but in rigorous population-based studies, reported rates may be as high as 37% to 41%, while others are somewhat lower (2,3). Research has found that chronic pain may have a strong negative impact on patients' emotional states and reduce quality of life (2-4). Chronic pain has also been associated with an array of psychopathologies, including depression, anxiety, personality disorders, decreased psychosocial function and substance abuse, although this relation may be better explained by a diathesis model (5).

Emotional and neuropsychological reactions to various conditions likely vary between and within populations. For example, reactions to

L'état affectif et neurocomportemental des patients ayant des douleurs chroniques

OBJECTIF : Examiner l'état affectif et neurocomportemental des patients ayant des douleurs chroniques.

MÉTHODOLOGIE : Les chercheurs ont étudié 15 patients de sexe masculin ayant des douleurs lombaires chroniques et 15 sujets témoins en santé pendant environ six mois. Ils ont mesuré la douleur au moyen d'une échelle analogique visuelle et évalué les effets neurocomportementaux de l'exposition environnementale et professionnelle à l'aide de la batterie des principaux tests neurocomportementaux (NCTB) de l'OMS.

RÉSULTATS : Les résultats de l'échelle analogique visuelle ont démontré une modeste plage de douleur déclarée (moyenne $\pm$ ÉT) de $62,0 \pm 10,8$ chez les patients ayant des douleurs chroniques, tandis que les sujets témoins ne déclaraient aucune douleur mesurable. Au moyen de la NCTB, les chercheurs ont découvert que les indices d'humeur négative, y compris la colère et l'hostilité, la dépression et le cafard, la fatigue et l'inertie et la tension et l'anxiété, étaient considérablement plus élevés chez les patients ayant des douleurs que chez les sujets témoins. Par contre, les indices de bonne humeur (vigueur et activité) des patients ayant des douleurs chroniques étaient inférieurs à ceux des sujets témoins. Les indices de la NCTB à l'égard des tests de dextérité et de motricité II de Santa Ana obtenus par les patients ayant des douleurs lombaires chroniques étaient inférieurs à ceux des sujets témoins. Les indices des autres sous-tests de la NCTB, y compris les tests de mémoire des chiffres, de rétention visuelle de Benton et des chiffres-symboles, ne donnaient pas de résultats significativement différents de ceux des sujets témoins.

CONCLUSIONS : Les patients ayant des douleurs lombaires chroniques étaient davantage d'humeur négative et moins d'humeur positive que les sujets témoins. Ces patients démontraient également des déficits neuromoteurs de coordination et de temps de réaction. D'autres études s'imposent pour examiner les mécanismes neurologiques et documenter les stratégies d'intervention potentielles auprès des patients ayant des douleurs chroniques.

chronic pain have been shown to differ according to demographic factors such as ethnicity (6). Pain is an understudied problem in certain highly vulnerable subpopulations including frail elderly patients, especially those with cognitive impairment, delirium or dementia (7). Compared with other negative emotions, anger may have a reciprocal relationship with chronic pain severity by increasing muscle tension near the site of injury, ie, through symptom-specific reactivity (8).

Anxiety has a direct effect on chronic pain patients' perception of their disability (2). There is a strong relationship among negative emotions, pain and functioning, particularly because pain interference affects depression (2). Chronic pain is characterized by multiple comorbidities and under-reporting of symptoms; as many as 45% to 80% of inpatients have pain that contributes to functional impairments. This makes pain evaluation very challenging. Multiple lines of evidence indicate that patients who present to chronic pain units frequently have personality features that make assessment and therapy difficult (9).

TABLE 1
Profile of Mood State (POMS) scores of chronic pain patients and control subjects

Item	Chronic pain patients (n=15)	Control subjects (n=15)	t	P
POMSA	17.60±10.95	7.80±3.99	3.256	0.003
POMSC	7.80±6.07	5.47±3.44	1.295	0.206
POMSD	20.33±13.17	6.27±4.43	3.920	0.001
POMSF	11.27±7.13	5.87±1.64	2.860	0.008
POMST	12.07±8.44	5.33±4.05	2.786	0.009
POMSV	15.27±6.32	21.70±6.53	-2.756	0.010

Data presented as mean ± SD. Domains: A Anger-hostility; C Confusion-bewilderment; D Depression-dejection; F Fatigue-inertia; T Tension-anxiety; V Vigour-activity

Chronic pain has also been associated with behavioural and cognitive impairments (7). Neurobehavioural testing is commonly recognized as a sensitive and valid method for detecting early dysfunction of the nervous system in connection with low-level exposure to neurotoxic agents, noise, stress and other exposures (10,11). One particular test battery, the WHO Neurobehavioral Core Test Battery (NCTB), is often used to examine the effects of various exposures (12,13). The NCTB is organized into seven subtests. These NCTB subtests include Profile of Mood States (POMS), Simple Reaction Time, Digit Span (DSP), Santa Ana Dexterity (SAN), Digit Symbol (DSY), Benton Visual Retention (BVR) and Pursuit Aiming II (PA). The purpose of the present article was to study the mood state and neurobehavioural changes in chronic pain patients to advance our understanding of chronic pain and facilitate novel treatment in these patients.

METHODS

Subjects

Subjects were recruited at Xuanwu Hospital in Beijing, China. Cases were sought at the outpatient pain clinic. Fifteen subjects were screened for inclusion using a visual analogue scale for clinically relevant pain. Other criteria for inclusion were right-handedness, nonsmoking status, and age between 26 and 45 years. All chronic pain patients included in the present study suffered from lower back pain for at least six months. Fifteen healthy subjects meeting the inclusion criteria without reports of pain were selected as the control group and matched for sex, income, handedness and smoking status. The average pain duration in chronic pain patients in the present study was 3.6 years. Subjects in both groups had between 13 and 15 years of education, a mean age of 41 years, and annual incomes of between RMB3000 and RMB5000. Subjects experiencing other diseases necessitating drug treatment or those presenting with high levels of alcohol consumption (500 mL ethanol/week or more) were excluded from the study.

The WHO-recommended NCTB was used for all test subjects in the present study. It has been translated and validated for use with Chinese-speaking subjects (10). The NCTB consists of two parts. One part is the six-section POMS questionnaire, which includes domains of anger-hostility (POMSA), confusion-bewilderment (POMSC), depression-dejection (POMSD), fatigue-inertia (POMSF), tension-anxiety (POMST) and vigour-activity (POMSV). These scales may all reflect psychological states in patients caused by chronic pain. The other part of the NCTB consists of six subtests: the DSP, which measures attention and auditory memory; the SAN, which tests manual coordination and speed; the DSY, a measure of cognition and motor speed; the BVR, which reflects visual cognition, and memory, coordination and speed; and the PA, another test of manual coordination and speed. The DSP is divided into DSPF (forward) and DSPB (backward); the SAN includes SANP (preferred hand) and SANN (non-preferred hand); and the PA includes PAC (correct) and PAE (errors).

TABLE 2
Scores of neurobehavioural tests of chronic pain patients and control subjects

Item	Chronic pain patients (n=15)	Control subjects (n=15)	t	P
DSP	19.47±4.16	21.20±2.60	1.37	0.182
SANP	58.87±13.71	69.27±10.20	2.36	0.026
SANN	62.33±14.89	75.47±14.74	2.43	0.022
DSY	18.13±10.33	22.20±7.15	1.25	0.220
BVR	7.07±1.10	6.60±1.12	1.15	0.260
PA	163.07±42.23	209.3±48.08	2.80	0.009

Data presented as mean ± SD. BVR Benton Visual Retention; DSP Digit Span; DSY Digit Symbol; PA Pursuit Aiming II; SANN Santa Ana Dexterity – nonpreferred hand; SANP Santa Ana Dexterity – preferred hand

The mean (± SD) visual analogue scale score for chronic pain patients was 62.0±10.8. The results of the POMS measurements for patients and control subjects are reported in Table 1. The POMSA, POMSD, POMSF and POMST scores in chronic pain patients were significantly higher than the corresponding scores in the control subjects ($P<0.05$). The POMSV score in chronic pain patients was significantly lower than that in the control subjects. By contrast, the POMSC score in chronic pain patients was not significantly different from that in the control subjects.

Results from neurobehavioural tests are reported in Table 2. SANP, SANN and PA scores in chronic pain patients were significantly lower than those of the control subjects. DSY, BVR and DSP of the chronic pain patients were similar to those in controls.

RESULTS

DISCUSSION

In clinical populations and research settings, most patients with chronic pain experience varying degrees of emotional distress (14). The most commonly reported forms of distress are feelings of anxiety and depression. Pain-induced depression has been shown to be a prognostic factor for long-term disability in patients with lower back pain (15). Anger, frustration and resentment are also reported, but these have received less attention in the literature (16). It is generally acknowledged that negative mood state modulates pain perception and may impact the effectiveness of pain management.

To our knowledge, no previous study has investigated the effects of chronic lower back pain on structured neurobehavioural measures across neuromotor and quantitatively defined ranges of emotional states. However, there are several studies that investigated the relationship between chronic pain and a negative mood state such as depression (15). As a stressor, chronic pain itself may induce negative mood states, which, in turn, affect biological and behavioural responses, which may provide feedback that will further negatively affect the patient's emotional responses. This might produce a vicious cycle with eventual disability and severe reductions in perceived quality of life as a consequence (17). It has been reported that serum cortisol levels are elevated or otherwise modulated in patients with chronic pain (18). This may be the result of stress-induced hypersecretion of corticotropin-releasing hormone, coupled with failure of negative feedback controls to limit the cortisol response (19). As a stressor, chronic pain and the related negative mood state both could induce cortical levels elevated in serum and salivary secretions (20,21).

In our study, high scores in the POMSA, POMSD, POMSF and POMST domains were seen among chronic pain patients compared with control subjects. Depression has been reported to be associated with higher levels of self-reported pain and pain behaviour, feelings of helplessness and loss of control, and poor response to treatment (22,23). Our neurobehavioural test results showed that pain patients had deficits in manual coordination and reaction speed, as shown in the results from the SANN, SANP and PA.

Previously, investigators have demonstrated (24) that chronic lower back pain is associated with impaired performance on a complex emotional decision-making task, suggesting abnormal prefrontal processing. Abnormal brain chemistry (25) and thalamocortical atrophy (26) has also been discovered in these patients. Coupled with our own findings, this literature suggested that clinical treatment of chronic pain should integrate mental health modalities, including psychological and psychiatric consultation (9).

Interpretation of our results warrants some caution because they are correlational and do not permit causal assertions. Also, our sample size is relatively small, which limited our ability to explore group differences on pain and social/occupational functioning. To better understand the relationship between chronic pain, neurobehavioural state, and long-term social and occupational outcomes, we suggest that future studies

build on the findings from our group and others via observational methods (eg, ecological approaches) that integrate quantitative psychometric and biological measures. Additionally, future studies that more specifically investigate the effects of pain on different cognitive functioning measures, as well as controls for mediating factors, will provide the field with valuable new knowledge that may help set the stage for the development of novel treatments for pain.
