TWO MERMITHERGATES OF ECTATOMMA

BY WILLIAM MORTON WHEELER¹

Since the publication in 1928 of my review of the modifications induced by Mermis parasites in various species of ants, two additional cases have been reported, one by Strelnikov (1928) in a Ponerine ant, *Pachycondyla striata*, from Paraguay, and one by myself (1929) in a Formicine ant, *Camponotus (Tanæmyrmex) punctatus* from Argentina. Two other interesting mermithergates have just come to light among some ants collected by Mr. Nathan Banks and Mr. P. J. Darlington. One of these belongs to the typical *Ectatomma tuberculatum* Olivier, the other to its variety *punctigerum* Emery. As long ago as 1890, Emery (1890 a) mentioned a peculiar worker of the typical *E. tuberculatum*, which we now know must have been a mermithergate, but he merely cites it as "analogous" to a similar specimen of *Neoponera villosa* with small head and voluminous abdomen.

The mermithized specimen of the typical *E. tuberculatum* was taken by Mr. Banks on July 15, 1924, near the tropical laboratory on Barro Colorado Island, Panama. It measures nearly 16 mm. and is of the same brownish ferruginous color as normal workers from the same locality, but with the gaster distinctly darker. The head is smaller and narrower, with scarcely an indication of the posterior angles and with very slightly larger and more convex eyes. Ocelli lacking. Antennal scapes extending half their length beyond the posterior corners of the head and the mandibles slightly narrower. Thorax shaped as in the normal worker but slightly less robust, with distinct, blunt teeth on the epinotum. Petiolar node more strongly compressed antero-posteriorly. Postpetiolar and gastric segments, especially

¹Contribution from the Entomological Laboratory of the Bussey Institution, Harvard University, No. 334.

the first, enlarged and distended with *Mermis*. Legs decidedly longer than in the normal worker.

Head sculpture peculiar in that the longitudinal rugæ are finer, closer together and decidedly more numerous on the front than in the normal worker. The reticulate rugæ on the sides of the vertex in the latter are also replaced by such longitudinal rugæ. Thoracic sculpture as in the normal worker. Petiolar node transversely rugulose and not irregularly rugose above. Postpetiole and gaster more opaque throughout, finely and densely striate, with a satiny lustre; the striæ transverse and converging behind on the postpetiole, longitudinal on the gastric segments. Venter more shining but very finely and transversely, though more superficially striate throughout. The sculpture of the abdomen therefore resembles that of the normal worker *tuberculatum*. The pilosity of the mermithergate is quite normal.

Although the typical form of *E. tuberculatum* is a common ant over a large portion of the Neotropical Region from Southern Mexico to Southern Brazil, its two varieties, *acrista* Forel and *punctigerum* Emery have a much more restricted distribution. The var. *acrista* is known only from Paraguay; Emery (1890 b) described *punctigerum* from a couple of workers taken by Simon at San Esteban, Venezuela. It is certainly the common, if not the only form of the species in Trinidad, where it has been taken by Prof. R. Thaxter and myself, and Dr. George Salt and Mr. Darlington brought me specimens of it from Northern Colombia. The worker differs from that of the typical *tuberculatum* in coloration, being decidedly darker and more brownish, and in the sculpture of the postpetiole and first gastric segment, the coarse, sparse punctures on which are larger, more impressed and interrupt the striated sculpture. Moreover, the striation on the first gastric segment is much feebler than in the typical *tuberculatum* and becomes obsolete on the sides, so that the whole segment is decidedly smoother and more shining. The female *punctigerum* (undescribed) is scarcely paler than the worker, with very similar abdominal sculpture though in some specimens the striation on the first gastric segment is even

normal female; d, mermithergate in profile; e, head of same.

feebler and the surface, therefore, even smoother and more shining.

The *punctigerum* mermithergate (Fig. 1d,e) was captured by Mr. Darlington on April 20, 1920 at St. Augustine, Trinidad, together with three normal workers of the variety. Were it not for this association the specific identity of the parasitized specimen might be doubtful, though its cephalic and thoracic sculpture is clearly of the *E. tuberculatum* type. The specimen measures 16.6 mm. in length and is longer than the average normal worker which measures only about 10-12.5 mm., but the proportions of the head, thorax and abdomen are very different. In the mermithergate the head measures only 3.2 mm. in length, including the mandibles, the thorax 4 mm., the abdomen 9.4 mm. The corresponding measurements of the normal large worker are: head 3.5 mm., thorax 4.5 mm., abdomen 4.5 mm. Though the head and thorax resemble those of the normal worker they are therefore decidedly smaller and more slender. The head, excluding the mandibles, is nearly square, very slightly longer than broad, with very feebly rounded sides and the posterior angles merely rounded-rectangular and not sharply rectangular or even distinctly cornuate as in the normal worker. Eyes larger, more protuberant, nearly hemispherical. There are no traces of ocelli. Antennal scapes extending nearly half their length beyond the posterior corners of the head (only two-fifths in the normal worker), mandibles somewhat narrower. Besides its smaller and more slender dimensions the thorax differs from that of the normal worker in having the lateral tubercles of the pronotum more acute and less auriculate, the median tubercle or projection narrower and more sharply defined. The base and declivity of the epinotum form a less distinct obtuse angle and the epinotal teeth are reduced to mere denticles. Petiole very similar to that of the normal worker but the node slightly more compressed anteroposteriorly. Postpetiole and gaster much larger and more voluminous, owing to their containing a large Mermis, the compact coils of which are visible through the distended intersegmental membranes. The hypertrophy affects not only the postpetiole and first gastric segment but also the deflected second, third and fourth gastric segments,

which in the normal worker and even in the female are much shorter and telescoped into one another. Anteroven-tral projection of the postpetiole less developed than in the normal worker and female; legs as long as those of the former.

Sculpture peculiar; the longitudinal rugæ on the front and vertex decidedly less coarse, denser and more numerous than in the normal worker, with the reticulate rugæ between the front and eyes also much finer; rugules on the median portion of the clypeus more numerous; striæ on the mandibles somewhat coarser. On the thorax the rugæ are distinctly finer and more definitely transverse; those on the posterior portion of the pronotum also transverse, not coarse and irregular as in the normal worker. The rugæ on the petiolar node are finer and symmetrical. On the postpetiole and gaster the sculpture is quite unlike that of *E. tuberculatum* and much like that of *E. quadridens* Fabr., the tergites of all the segments being finely and regularly striate, so that the surface is subopaque, with a faint satiny lustre. The striæ on the postpetiole are arcuate anteriorly, longitudinal in the middle and transverse posteriorly; on the first gastric segment longitudinal anteriorly and transverse behind; on the second and third gastric segments transverse and more oblique on the sides. The fourth segment is more shining, with finer and less distinct striæ. The coarse punctures on the postpetiole and first gastric segment are small, inconspicuous and scattered, as in *E. quadridens* and therefore very different from those of *punctigerum* or the typical *tuberculatum*.

Pilosity as in the normal *punctigerum* worker, but less abundant, especially on the abdomen.

Coloration decidedly darker; dark brown, almost blackish, with brownish yellow clypeus and mandibles, the former streaked with fuscous in the middle, the latter fuscous externally. Femora, terminal tarsal joints, tips of scapes, apical halves of antennal funiculi and borders of gastric segments reddish brown; a spot on the middorsal region of the postpetiole and one on the corresponding region of the first gastric-segment more yellowish.

The specimens described in the preceding paragraphs are obviously modified workers, without any perceptible female

(queen) characters. Even the enlargement of the abdomen is quite unlike that of the normal *Ectatomma* female, since in this caste the gaster is shaped like that of the worker, though more voluminous, especially in the region of the postpetiole and first gastric segment. The mermithergates are interesting for two reasons, first, because they so clearly illustrate the compensatory decrease in the size of the head and, in Darlington's specimen, also of the thorax as a result of the hypertrophy of the abdomen, which harbors the *Mermis*, and second, on account of their close resemblance in coloration, abdominal sculpture, and, I may add, also in the shape of the posterior portion of the head, to another species of the same genus, *E. quadridens*. This singular resemblance may, I believe, be most readily explained on the supposition that the specific characters of *quadridens* are probably more nearly those of the ancestral species of *Ectatomma* and that in the mermithized specimens these characters have been activated as a result of metabolic disturbances set up during metamorphosis by the parasite. To have produced such a pronounced effect on the characters of the adult ant, the young nematode must have entered its body cavity during the larval stage. Recently Vandel (1927) has maintained that in *Pheidole pallidula* infection of the prepupa by the *Mermis* is sufficient to produce a mermithergate, but his evidence for this contention is very meager. I have called attention to the fact (1928) that the larvæ of the Ponerinæ and Formiciæ (*Lasius*) spin cocoons before the prepupal stage and that it is therefore very improbable that the young nematode would wait to bore through a tough envelope when it could so easily and directly enter the unprotected, thin-skinned larva. That this is actually what happens, has been shown by Dr. N. A. Cobb, our well-known authority on the nematodes, who writes me that he has found the larva of *Allomermis myrmecophila* Bayliss—"in the body cavity of a queen grub of the dark-colored *Lasius* from Falmouth, *Lasius niger neoniger*." Falmouth, Massachusetts, is the locality in which Dr. A. H. Sturtevant found the many mermithized queens (mermithogynes) of *Lasius* described in my paper of 1928.
