OCCUPANCY BY HYLAEUS OF SUBTERRANEAN HALICTID NESTS (HYMENOPTERA: APOIDEA)¹

Hylaeus (Colletidae) is well known to nest in various preformed cavities. It is most commonly reported in hollow stems (Stoekhert, 1933; Malyshev, 1936; Michener, 1965; Stephen et al., 1969) but also may occupy cynipid wasp galls (Stoekhert, 1933; Laroca, 1971) and dead wood (Perkins, 1899; Michener, 1965). However, nest sites are not limited to plant materials. Smith (1855) reported cells in hollow pieces of "flint stone"; Ferton (1932), in earthworm burrows; and Perkins (1899), in ground. The present paper concerns nests of H. bisinuatus in burrows of a halictine bee in an earthen bank; this is the first record of Hylaeus occupancy of nests of another hymenopteran.

H. bisinuatus has also been found in North America nesting in soda-straw traps and nail holes (R. R. Snelling, pers. comm.) and in Europe in hollow briar (Rubus) stems (Stoekhert, 1933). Thus this species evidently has behavior which is flexible enough to enable it to nest in a variety of preformed holes in a wide geographical area.

In early July to early August, 1974, six nests of H. bisinuatus were found among those of Lasioglossum (Dialictus) zephyrum (Halictidae: Halictinae) in a nesting aggregation in vertical banks of the Kansas River, near Eudora, Douglas County, Kansas. Although the Lasioglossum nest aggregation is enormous, extending for about 1 km up and down the river, all the Hylaeus nests were found in about 10 square meters where the bank faces northwest.

The burrows occupied by H. bisinuatus were obviously former nests of L. zephyrum. In two nests vacant cells of L. zephyrum were near those used by H. bisinuatus; abandoned cells of L. zephyrum probably would have been found in all nests by following main burrows farther into the soil. Cells of Hylaeus were constructed in cells of the Lasioglossum still having the shape and wax-like lining

²H. bisinuatus ( Förster, 1871), described from Europe, is a senior synonym of H. steensi (Crawford, 1913), described from North America, where it is probably adventive (R. R. Snelling, pers. comm.).

characteristic of the halictine. The longitudinal axes of the burrows and cells of the nests were horizontal as is typical for nests of L. zephyrum in vertical banks (Batra, 1966). Burrows and nest entrances were similar in size to those of L. zephyrum. Thus there is no evidence that the Hylaeus did any nest excavation; it appears to have merely used available nests for its own purposes. Furthermore there is no evidence that the Hylaeus entered occupied Lasioglossum nests, although this possibility exists.

All six Hylaeus nests were discovered after their entrances had been closed, each with a sheet of a cellophane-like material flush with the surface of the soil bank. The sheets had striations radiating from their centers and small openings along their margins. A female of H. bisinuatus was discovered licking across a nest entrance already closed by a "cellophane" sheet. Evidently she was finishing the closure. She revolved around the entrance 3 times in 18 minutes while she licked 22.5 times per minute (n = 2 min) across the sheet; during this time she took occasional rests of several seconds each. During each lick the tip of her proboscis moved from her midventral area to a point in front of her head.

For identification she was captured before she finished the closure and two days later (on 5 July) her nest was examined (Fig. 1). All three of the cells in her nest were provisioned with a soft yellow material, most likely a mixture of pollen and nectar as is used by

other *Hylaeus*, and each contained a larva. One larva became a prepupa on 6 July, a pupa on 7 July, and an adult female on 14 July; the other larvae were small and died.

Nests had from 1 to 3 *Hylaeus* cells ($\bar{x} = 1.7, n = 6$ nests), each in a different *Lasioglossum* cell (Fig. 2). Both *Hylaeus* cells which were measured were 5 mm long and 3.5 mm in maximum diameter and at the ends of *Lasioglossum* cells. The walls of the cells had old wax-like lining deposited by *L. zephyrum* (Batra, 1966). *H. bisinuatus* laid down two other cell linings to form its cells: (1) a very thin "cellophane" layer visible under a microscope ($30 \times$) only when light strikes it at a certain angle and (2) a slightly thicker "cellophane" layer over the first one. This thicker layer also covered walls of lateral burrows and parts of main burrows. A sheet of what appeared to be this same second layer closed off each cell and with the unaided eye the halictine cells appeared to be constricted where such a sheet was placed. Complete removal of the cellophane-like material, however, shows the unmodified form of the halictine cell.

*H. bisinuatus* used cells of *L. zephyrum* that were 0.8 to 4.5 cm ($\bar{x} = 3.3$ cm, $n = 6$ nests) from the nest entrances. Since *L. zephyrum* constructs cells this close to the surface of a soil bank only in spring or early summer, the *Hylaeus* must have used early-season *Lasioglossum* cells made in the year of this study or possibly in the previous year.

Acknowledgments

I thank Mr. Roy R. Snelling of the Los Angeles County Museum of Natural History for identifying *Hylaeus bisinuatus*. He and Drs. Charles D. Michener and William J. Bell and Ms. Marjorie R. Chabot made important suggestions regarding this note. It is a byproduct of National Science Grant GB-38502 (W. J. Bell and C. D. Michener, coprincipal investigators).
