Abstract

Purpose. We conducted a systematic search of published literature, to assess (i) quality of life (QoL) for survivors of a bone tumour compared with the normal population; (ii) QoL implications following amputation, successful or failed limb salvage; (iii) adaptation of young children to amputation compared with older children or adolescents.

Methods. Electronic databases were searched including Medline, PsycLIT and Cinahl covering the years 1982–1998.

Results. We identified 11 studies. Regardless of treatment, physical functioning was poor compared with population norms or healthy siblings. There was less consistent evidence regarding emotional functioning. Seven studies compared functioning in amputees and limb salvage patients. Two reported advantages in physical function for the limb salvage group, one for the amputees and the rest no differences. Evidence about social functioning or marriage is inconclusive, but there are suggestions that amputees report more job discrimination.

Discussion. The literature is inconclusive, largely because of methodological problems. These include small and non-representative samples, and lack of sensitive and appropriate measures. Specific gaps in the literature include very little work concerned with psychological outcomes for children, or for those experiencing failed limb salvage. More attention needs to be given to gender differences in emotional response to traumatic surgery. The implications of the results for helping families balance the merits of different treatments are discussed.

Introduction

The issue of quality of life (QoL) following treatment for cancer has been extensively discussed. QoL may be compromised by physical complications associated with the initial disease or late side-effects of chemotherapy. QoL may also be compromised psychologically as a result of concerns about relapse or recurrence. Survivors may experience prejudice and limited work opportunities, restricted social lives or opportunities to travel. For these reasons, there have been a number of follow-ups of survivors of cancer generally, and there is now considerable evidence relating physical and psychological sequelae to radiotherapy or specific chemotherapy protocols.¹

In addition to the difficulties experienced by survivors of any cancer, those treated for a bone tumour may experience additional threats to QoL as a consequence of restricted mobility, pain and stigmatization. With modern chemotherapy, survival rates approaching 60–65% can now be achieved for patients with bone tumours. Some 85% are offered limb salvage surgery and the remainder amputation. Patients treated with limb salvage have been shown to have a slightly higher rate of recurrence compared

with those treated by amputation, although overall survival rates are comparable.² However, endoprostheses can fail with the result that many patients may ultimately need amputation.

The decision to amputate or treat by limb salvage is complex. Neither treatment appears to be associated with improved survival. Amputation may be the preferred option for those who wish to participate in many physical activities including contact sports (an artificial limb can relatively easily be replaced). In contrast, limb salvage has the merit of preserving body image, and the decision to amputate can subsequently be taken at any time. However, salvaged limbs vary in function, and many patients are so concerned about breakages that they adopt very sedentary life-styles. Wherever it is practically possible to perform limb salvage, this option is likely to be preferred by clinicians, parents and patients, as well as being less expensive than amputation.⁴¹ Failed limb salvage procedures are potentially problematic for patients emotionally, in that they may feel that they have failed their surgeon in some way, that they have contributed personally to the failure through their own recklessness or that the years of struggling

with the endoprosthesis amounted to a waste of time.

The concept of QoL is itself elusive, dismissed by some as 'a kind of umbrella under which are placed many different indexes with whatever the user wants to focus on'.³ For others, QoL is a necessary and important outcome measure offering a balance to earlier emphases on survival statistics and morbidity.^{4,5} There is a general consensus that QoL is a multidimensional concept involving physical, psychological and social elements and most measures include domains to assess each of these separately. Critically, QoL assessments must include information from the patient about their own perceptions of the impact of disease on their lives.

The demand for measures of QoL has far outweighed the level of sophistication of research or theory in the area: 'The term "health-related quality of life" was coined as a way of justifying the use of currently available measures under a new banner'.⁶ The emphasis is very much on functional capacity, reflecting the traditional approach to assessing medical outcomes. Thus the focus is on the ability to perform everyday tasks and fulfil occupational and social roles. This focus on functional capacity ignores the relative meaning of these tasks to the individual, and assumes there is an optimal level of functioning to which everyone aspires. In order to balance this functional bias, QoL measures need to include some assessment of the meaning of the illness to the individual.

Since there are currently few comprehensive measures of health-related QoL available, it is necessary to rely on proxy measures, including for example physical function (physical symptoms and pain); psychological function (anxiety, depression or body image); and social function (employment, social relations or marital status).

While there may be disagreements about measurement, the issue of QoL is of central concern both to surgeons, patients and their families. Clinically, a number of questions may be raised on a daily basis.

- How does treatment for a bone tumour affect an individual's QoL?
- How does QoL differ between amputees, successful limb salvage and failed limb salvage?
- Do young children adapt better to amputation than older children or adolescents?

This paper reports the results of a systematic search of current literature with the aim of assessing current findings relating to these questions. In addition, methodological problems are identified and recommendations made about future work.

Method

The following electronic databases were searched: Medline, PsycLIT and Cinahl covering the years 1982–1998. Search terms included QoL, health status, functional status, well-being, bone tumour, osteosarcoma, Ewing's tumour and were subsequently

modified to meet the requirements of the different databases. We also examined reference lists in reviews to identify other relevant studies. A data extraction sheet was used to summarize the methods and results and the data were organized using Reference Manager.

Inclusion and exclusion criteria

Given the limited research in the area, no restrictions were placed on study design or methods. However, papers which reported clinical or survival data but no psychological data were excluded, as were descriptive accounts which did not include any statistical analyses. Papers were included which involved statistical comparisons (1) with groups (e.g. healthy siblings) or population norms, and (2) between groups undergoing different treatment options (amputation or limb salvage).

Results

We identified 11 studies, which are summarized chronologically in Table 1.^{18–39} Methods included comparisons with population norms, well siblings, and between amputee and limb salvage patients. Eight of the 11 studies made comparisons against population norms. Both Nicholson *et al.*⁹ and Novakovic *et al.*¹⁵ included a comparison group of well siblings. One study only involved comparisons between amputees and limb salvage groups.¹⁷

How does treatment for a bone tumour affect an individual's QoL?

Physical functioning

Seven studies attempted to measure physical function. Three used the Functional Evaluation of Reconstructive Procedures,³² and measures by Butterfield (unpublished) or Karnofsky³⁶ were each used in one study. The physical function subscale of the SF36³⁵ was used in one study.¹⁴ Three studies assessed function on the basis of a semi-structured interview.^{10,11,14}

In the two studies where comparisons were made with healthy siblings,^{9,15} there was evidence that the bone tumour group had poorer physical function than their siblings. These included specific difficulties climbing stairs,⁹ and 'general physical function'.¹⁵ Thirty patients treated by limb salvage showed significant problems on a number of domains including physical functioning and physical role performance, pain, general health and social functioning compared with British norms.¹⁴

Emotional functioning

Four studies reported no differences between survivors and population norms^{8,11,12,14} based on standardized measures of anxiety or depression.

15. Novacovic <i>et al.</i> , 1997	89			97 siblings		Education, employment, marriage, fertility, treatment related difficulties. Function ³⁶	No differences in educational achievement. Survivors less likely to be employed full-time, married or have children. Function poor compared with siblings
16. Felder-Puig <i>et al.</i> , 1998	60 response rate=54%, 49 limb salvage and 11 amputation	Age at diagnosis=15.27range=3 months–25 years; Age on testing=23.5 years, range=15–30 years	Self		'Extremities'	Selected parts of Subjective well-being; ³⁷ Anxiety; ³⁸ Self-concept; ³⁹ Life goals; ⁴⁰ Interview	No differences based on surgery, gender, time since treatment and recurrence. Those diagnosed in adolescence had more problems than those diagnosed in childhood or early adulthood. Non-respondents were more likely to have had amputation.
17. Johansen <i>et al.</i> , 1998	58 amputees; 89 limb salvage	At time of study: LS=50, (14–87); amp=47 (14–88) age at surgery not given.	Self		Upper and lower limb	Functional assessment ³²	Limb salvage patients had significantly higher functional score than amputees (85 vs 47)

However, three of these studies reported that a number of individuals sought professional help to deal with emotional problems surrounding their surgery.^{11,12,14}

How does QoL differ between amputees, successful limb salvage and failed limb salvage?

Physical functioning

Six studies reported comparisons between those treated by amputation and limb salvage. Physical function was reported to be better for the limb salvage group in two studies^{12,17} and for the amputee group in one study.¹³ Three studies reported no differences.^{7,8,10} It should be noted that in two studies where a specific measure of function was used,^{12,17} differences in favour of the limb salvage group were reported. A generic instrument may lack sensitivity in this context⁷ and a non-standardized interview¹³ may be less likely to yield reliable data.

Two studies assessed function only in patients with limb salvage.^{11,14} Most (80%) were able to resume their previous activities. However, 16% could only walk 50–100 feet.¹¹ Difficulties running (88%), swimming (49%) and riding a bike (46%) were reported.¹⁴

Pain

Half of the patients interviewed by Greenberg *et al.*¹¹ reported pain, though most of these described negligible or mild pain. Eiser *et al.*¹⁴ reported that 24% of a group of patients treated by limb salvage experienced no pain, 7% reported pain when it was cold, and 15% only experienced pain after strenuous exercise. Nineteen reported serious and continuous pain, with 10 of these reporting occasional or regular use of analgesics. Rougraff *et al.*¹² found that 25 of 29 patients reported no pain and there were no differences between the amputation and limb salvage groups.

Psychological functioning

Felder-Puig *et al.*¹⁶ used standardized German measures to calculate indices of emotional well-being, social well-being, love life and subjective capabilities and reported no differences as a function of type of treatment. Similar results were found for measures of adjustment to illness, perceived impact of illness, and activities of daily living⁷ and for mood, adjustment to illness or psychiatric symptoms.^{8,10,12}

Based on interview data, Eiser *et al.*¹⁴ reported that 25 of 41 patients treated by limb salvage were distressed about the physical appearance of their leg. A small number (mostly women) always chose clothes to hide their leg (long trousers or skirts).

Social functioning

Nicholson *et al.*⁹ found no differences in employment, income or marriage rates compared with

siblings, but all other reports have suggested compromised levels of functioning. Felder-Puig *et al.*¹⁶ reported that patients were less likely to be married, more likely to remain at home with parents and less likely to have children compared with population statistics. Level of education was similar and incomes appeared comparable. However, 18% had given up work because of treatment, and 27% had changed their type of work. Many reported difficulties in obtaining work. Lower level of education, single marital status or lower salary were all seen to be a consequence of the illness.¹² Novakovic¹⁵ did find that survivors (all Ewing's sarcoma) were less likely to be employed full-time, to be married or have children compared with siblings. However, there were no differences in insurance status or use of health care services. Amputees felt they were not employed at an appropriate level and they were also less likely to have married.¹³ Amputees reported more work and social discrimination compared with the limb salvage group and were more socially isolated.¹⁰ Fourteen of 40 limb salvage patients interviewed about their work felt that they were limited because of their illness, mostly those with lower education levels.¹⁴

Most studies do not provide data on sexual functioning. However, limb salvage patients reported greater reduction in sexual functioning compared with amputees.⁷ Patients treated in the early days of limb salvage surgery often had stiff, painful or oedematous legs following radiotherapy, and direct comparisons with more recently treated patients should therefore not be attempted. Most patients had sexual experience and reported few problems with sexual functioning, but amputees were less likely than limb salvage patients to have married.¹³ Clearly, these data are difficult to collect and self-reports may be subject to considerable bias.

Greenberg *et al.*¹¹ noted that patients generally were positive about limb salvage compared with amputation, and were prepared to spend months in hospital to try to preserve the limb. Patients were asked to rate on a five-point scale whether the efforts to save the limb had been worthwhile. Mean ratings were highest (indicating most positive ratings) for those with successful limb salvage (4.5) compared with those treated by amputation (3.6). Those who experienced amputation following failed limb salvage still rated the effort as very worthwhile (4.0). Only one of the patients actively chose amputation. Satisfaction remained high, even among those who experienced amputation following a failed prosthesis.¹¹ There was some opinion that the time involved in trying to save the limb allowed the patient the opportunity to adjust to the possibility of limb loss. In the context of failed limb salvage, patients also reported that it was important to make known their own preferences about amputation to surgeons, given the previous investment in preserving the limb.

Some recognized that surgeons were disappointed and therefore often reluctant to accept the need for amputation.

Do young children adapt better to amputation than older children or adolescents?

The assertion that young children adapt quickly following amputation is common, but we found little evidence to support the view. 'Children quickly adapt to detachable limb prosthesis and after a short period acquire remarkable agility' (Pinkerton *et al.*⁴², p.176). Circumstantial evidence is provided by Felder-Puig *et al.*¹⁶, who reported that patients diagnosed as children (<13 years) had fewer problems (as measured by social well-being) than those diagnosed during adolescence (14–19 years). There was no comparable effect on their measure of physical well-being. No other paper addresses this question.

Comment on methods

There are substantial difficulties inherent in conducting psychosocial work in this area. It is not possible to conduct randomized control trials and assign patients to different treatment options. Simple comparisons between populations differing in surgery are inevitably confounded by demographic and clinical differences between groups, which may contribute more to psychological difficulties than the surgical procedures of primary interest. In addition, conventional questionnaires do not adequately address the question. The development of appropriate and sensitive QoL measures for use with this population has to be a priority for future work. Without such measures, we lack tools to assess QoL outcomes between patients experiencing different treatments, or to evaluate any intervention programmes.

Given the above reservations, limitations in the current literature need to be recognized, some of which make interpretation of the findings problematic. First, participation rates are often less than ideal, and this raises questions about the representativeness of findings. This partly reflects relatively poor survival rates, particularly in Ewing's tumour, and partly also difficulties in tracing patients who have not been involved in active follow-up many years after treatment. The possibility that those who are traced and are willing to be involved have a different quality of life from those who cannot be located or do not respond to requests to participate, has to be considered.

Probably for a number of reasons, information about non-participants is rarely reported. Where it is available, it is invariably limited to brief demographic or clinical variables. Based on such analyses, most studies report no differences between those who do and do not participate.^{8,13,14} These comparisons are based on very broad and often initial indicators of disease and may not reflect ongoing differences

between the groups. More detailed follow-up was provided by Felder-Puig *et al.*¹⁶ who followed up non-participants by phone. Non-participants were more likely to be amputees, more likely to be depressed and had higher rates of substance abuse and legal difficulties compared with participants. In a separate study, refusers were more likely to be male, and to have higher rates of substance abuse and legal difficulties.¹¹

Second, a relatively large number of outcome measures have been employed. This reflects the lack of suitable instruments available and failure to specify the ways in which quality of life may be most likely to be affected. We need to move away from functionally orientated QoL measures and adopt more process orientated models that recognize patients' capacity to re-appraise their lives and adjust to their current health status.⁴³

Third, very few studies have included patients who were treated as children. Patients were diagnosed before 20, 21 and 24 years, respectively;^{7,9,13} the sample described by Eiser *et al.*¹⁴ included those diagnosed between 5 and 14 years. In other cases, some young children and adolescents were included, but for analyses all patients regardless of age are treated as a homogenous group. This approach fails to address the specific issues that affect children and young people following amputation or limb salvage surgery, relating especially to issues of body image, mobility and social functioning. It is one thing to lose a leg when established in work and social relationships; it is quite another if, as an adolescent, it is necessary to negotiate entrance to the adult world of work and social relationships. Outcome measures need to be sensitive to developmental issues. There is no empirical evidence regarding how well children adapt to surgery compared with adults. This kind of work is needed in order to develop appropriate physiotherapy and promote successful adaptation among younger patients and to consider service needs for child patients.

Fourth, in many studies sample sizes may be so small that it would not be possible to identify differences between groups. Calculations of effect sizes should be made so that it is clear that the sample is large enough that any underlying differences can be identified. In practice, it may be naive to make simple comparisons between groups who have been treated by limb salvage or amputation. Limb salvage is invariably the treatment of choice. This means that patients who experience an amputation are likely to have first experienced many months of limb salvage. Acceptance of the amputation may therefore be influenced by their experiences of limb salvage. While some may interpret the need for amputation as a failure, others will see the earlier experience as essential in aiding adjustment to the loss of the limb. We would like to reiterate our point that these are not questions that can be answered by adopting conventional

experimental designs, but require more innovative research methods.

Fifth, there are difficulties in interpreting studies involving comparisons of employment, education level or marital status, either against population statistics or between treatment groups. To any independent observer, it is clear that treatment for a bone tumour, whether amputation or limb salvage, will adversely affect an individual's job prospects. The fact that more patients do not report difficulties is a testament to individual resilience and adaptability.

Conclusions

Given the importance of failed limb salvage, it is disappointing that so little research has attempted to determine the psychological impact for the patient and the family of failed limb salvage surgery. Above all, this situation requires a good relationship between patient and surgeon, in that both must recognize the need to maximize function and improve QoL. Either the patient or the surgeon may assume that the other has more invested in preserving the limb. Considerable sensitivity is called for in opening negotiations about amputation, and patients may need considerable time to adjust to the need for further surgery. Contrary to the view that failed limb salvage will be emotionally problematic for patients, it may well be that better outcomes are possible where patients feel they made their own decision about surgery.

One of the merits of the systematic review method is the identification of gaps in the available literature. We include in this the lack of attention to the specific needs of children and their families. Without exception, research has included patients several years after their initial treatment. This means that we know little about the initial impact of treatment, how patients adapt to their surgery or how they set about rebuilding their lives. Although there is an assumption that surgery affects body image, this has rarely been systematically assessed.

The issue of gender differences in adjustment has not been consistently addressed. Any chronic illness which limits physical functioning may be more detrimental for the QoL of males compared with females, since it might compromise opportunities for males to participate in team sports and aggressive games. In contrast, amputation may have a worse impact on QoL for females, assuming the greater importance of body image.^{13,14} Females appeared to adjust as well as males, though they also reported more anxiety about how others might react to them.¹³ Differences are not likely to be limited to participation in sports, but comprehensive assessment must include a range of activities, including social as well as physical functioning. In contemporary society and our world of 'equal opportunities', we perhaps should not expect that the consequences of surgery will be related to gender. However, we need to acknowledge

a substantial body of literature that attests to differences in emotional response and coping preferences following trauma between men and women.⁴⁴

The results of follow-up studies describing the QoL of survivors of bone tumours is potentially useful in order to provide information to new patients about likely outcomes and the expected course of events. For surgeons, such information may aid decision making and guide the way in which information is presented to new patients. The papers reviewed provide some information about physical and psychological outcomes, although interpretation needs to be made with care, given the methodological limitations inherent in most work.

Although there have been a number of studies describing physical and psychological outcomes following treatment for bone tumour, little is directly relevant to clinical issues. Questions such as how well young children adapt following amputation, or the effects of failed limb salvage have been rarely addressed. It is important that future research addresses these issues directly rather than focus generally on psychosocial adjustment.
