KEYWORDS: lymphangioleiomyomatosis, tuberous sclerosis complex, polycystic kidney disease

Received November 15, 2006; Accepted December 12, 2006; Published January 26, 2007

The following images are from a 32-year-old woman with cystic lung disease, chylothorax, and cystic kidney disease leading to bilateral nephrectomies. CT imaging reveals extensive thin-walled cysts throughout the entire lung parenchyma (Figure 1), while the left kidney is similarly riddled with cysts and angiomyolipoma (Figure 2). Lung biopsy was consistent with lymphangioleiomyomatosis, and renal pathology revealed polycystic kidney with angiomyolipomas consisting predominantly of smooth muscle with areas of fat and vasculature.

Lymphangioleiomyomatosis (LAM), a disease of predominantly women, is characterized in the lung by cysts, pneumothoraces, and chylous pleural effusions. Lymphangioleiomyomatosis (LAM) is characterized by abnormal smooth muscle cell proliferation, leading to cystic destruction of the lung and eventual respiratory failure. Other organ system manifestations include angiomyolipomas in the kidneys, which can also occur in the tuberous sclerosis complex (TSC). TSC, an autosomal dominant neurocutaneous disorder, arises from mutation in the *TSC1* (hamartin) or *TSC2* (tuberin) gene, the latter of which is commonly seen in patients with LAM[1]. One-third of patients with TSC have evidence of pulmonary cysts on imaging of the chest, despite lacking respiratory symptoms[2].

TSC is frequently associated with renal cysts. *PKD1*, which is one of the genes responsible for autosomal-dominant polycystic kidney disease (PKD), lies adjacent to *TSC2*, and deletions in both genes lead to development of the recently described *TSC2/PKD1* contiguous gene syndrome[3,4]. While there have been no studies in the literature thus far documenting a direct association between LAM and PKD, these two diseases and TSC may all be linked by the close proximity of the *TSC2* and *PKD1* genes.

APPENDIX

Editor Comment

Because of the unique importance of these images, which are amenable to different interpretation, we are including the comments of the reviewers.

Daniel Batlle, M.D.

Reviewer's commentary:

Ref. 1

While the diagnosis of Tuberous Sclerosis (TSC) is suspected in association with Polycystic Kidney Disease (PKD), the main diagnosis in this patient, the lack of other skin or CNS manifestations to support a diagnosis of TSC opens the possibility that the patient indeed has isolated Lymphangioleiomyomatosis (LAM) as proposed by the authors. It is important to be aware of the LAM/TSC complex.

Ref. 2

The authors describe interesting images of the lungs and kidneys with cystic formation from a patient who has either Lymphangioleiomyomatosis (LAM), Tuberous Sclerosis (TSC) or both. The authors favor the diagnosis of isolated LAM with associated angiomyolipomas and polycystic kidney disease (PKD) (three diseases). We favor the possibility that this is a case of LAM/TSC, because PKD is not seen in patients with isolated LAM. By contrast, PKD has been described often with TSC (1,2). Angiomyolipomas are seen in both isolated LAM, and LAM/TSC.

It is important to recognize that some authors consider LAM a partial form of TSC (*form fruste*), since there is overlap in between these two entities (1,2).
