Like many new concepts, especially those that break old dogmas, it took some time for the scientific community to accept the existence and functional significance of G-protein–coupled receptor (GPCR) heteromerization (for a recent review, see Ferré et al.[1]). As reviewed in four manuscripts of this “NIDA Special Issue”, it is becoming clear that GPCR heteromerization plays a very important role in central nervous system (CNS) function and that GPCR heteromers can become invaluable targets for drug therapy.

Very often when an important new concept is generally accepted, numerous claims of its paternity appear, often by scientists that initially were completely against its acceptance. In the present issue, Franco et al.[2] provide an historical account of the discovery of receptor heteromers. It was at the beginning of the 1990s that Agnati, Fuxe, and coworkers hypothesized that their initially discovered “intramembrane receptor-receptor interactions” (reviewed in Agnati et al.[3]) required a close intermolecular cross-talk, which implied receptor heteromerization[4]. Fluorescence and Bioluminescence Resonance Energy Transfer (FRET and BRET) techniques allowed the demonstration of receptor heteromers in transfected cells in culture[5], but these techniques could not be applied *in situ* in natural tissues. Therefore, a major challenge has been the identification of receptor heteromers in the brain. Franco et al. review the concept of “biochemical fingerprint”, the most useful practical method to detect receptor heteromers in the brain[2]. Basically, this method involves the identification of a biochemical characteristic of the receptor heteromer in the brain after its initial demonstration in an artificial cell system. In fact, intramembrane receptor-receptor interactions constitute a common biochemical fingerprint of receptor heteromers[1,2,3].

The biochemical fingerprint of the dopamine D₁-D₂ receptor heteromer, reviewed by George and O’Dowd[6], is its characteristic G-protein coupling (G_{q/11}), which leads to a specific calcium-dependent PLC signaling pathway. The discovery of the D₁-D₂ receptor heteromer provided an explanation for previous experimental findings that show the ability of D₁ receptors to couple to G_{q/11} in native tissue, but not in transfected cells expressing D₁, but not D₂ receptors[7]. An additional discovery about the D₁-D₂ receptor heteromer is that it can be selectively activated by specific ligands[7]. Conceptually, this illustrates a very important property of receptor heteromers: They can be targeted by specific drugs. Therefore, identification of receptor heteromers that modulate brain functional units particularly involved in brain dysfunction becomes an important goal in the field.

Heteromerization of mu and delta opioid receptors (μO and δO receptors, respectively) also promote the formation of novel signaling, as reviewed by Rozenfeld et al.[8]. Activation of μO receptors leads to a G-protein–mediated rapid and transient MAPK activation, while activation of μO-δO receptor heteromers

leads to a switch to a G-protein-independent and β -arrestin-mediated delayed, but sustained, MAPK activation[9]. A number of studies indicate that morphine tolerance correlates with formation of μ O- δ O receptor heteromers, and Rozenfeld et al. suggest that a switch to the β -arrestin-mediated signaling contributes to the changes in morphine response that underlie tolerance[8]. In fact, targeting the μ O- δ O receptor heteromer with morphine, which activates μ O receptor, plus a δ O receptor antagonist, diminishes morphine tolerance and enhances analgesia[8].

As reviewed by Ferré et al.[10], the various localizations (synaptic, extrasynaptic), sources (neurons, glial cells), and modes of neurotransmission (synaptic and extrasynaptic) impinging on the receptor heteromers allow them to play a key role in the processing of computations performed by local modules, defined as the minimal portion of one or more neurons and/or one or more glial cells that operates as an independent integrative unit[11]. Ferré et al. provide an example of the integrative role of adenosine receptor heteromers as processors of information in the striatal spine module[10]. Targeting those adenosine receptor heteromers might provide new treatments for basal ganglia disorders and drug addiction. In fact, targeting the adenosine A_{2A} - D_2 receptor heteromer with a dopamine agonist (L-dopa) plus an A_{2A} receptor antagonist is being shown to be successful in clinical trials in Parkinson's disease[12].
