Salicylic acid (SA) is an elicitor to induce the biosynthesis of secondary metabolites in plant cells. Hydrogen peroxide (H$_2$O$_2$) plays an important role as a key signaling molecule in response to various stimuli and is involved in the accumulation of secondary metabolites. However, the relationship between them is unclear and their synergetic functions on accumulation of secondary metabolites are unknown. In this paper, the roles of SA and H$_2$O$_2$ in rosmarinic acid (RA) production in Salvia miltiorrhiza cell cultures were investigated. The results showed that SA significantly enhanced H$_2$O$_2$ production, phenylalanine ammonia-lyase (PAL) activity, and RA accumulation. Exogenous H$_2$O$_2$ could also promote PAL activity and enhance RA production. If H$_2$O$_2$ production was inhibited by NADPH oxidase inhibitor (IMD) or scavenged by quencher (DMTU), RA accumulation would be blocked. These results indicated that H$_2$O$_2$ is a secondary messenger for signal transduction, which can be induced by SA, significantly and promotes RA accumulation.

1. Introduction

Salicylic acid (SA) is often used to regulate plant growth and development, seed germination, and fruit formation and to enhance the capability of the plants to respond to abiotic and biotic stresses [1, 2]. Exogenous application of SA can promote the thermo tolerance of mustard seedlings [3], chilling tolerance of cucumber [4], salt stress of Arabidopsis seedlings [5], and toxicity tolerance of cadmium of barley seedlings [6]. In recent years, SA has been used as an elicitor to induce the biosynthesis of secondary metabolites in plants. Exogenous application of SA induces the biosynthesis of coumarins in Matricaria chamomilla [7], taxane in Taxus chinensis [8], saponins in ginseng [9], phenolic acids in Salvia miltiorrhiza [10], artemisinin in Artemisia annua [11], and sinapyl alcohol in ulmus cells [12].

The biosynthesis of secondary metabolites in plant cells is regulated by specific signal transduction pathways. Under the stimulation of elicitors, some biochemical events related to signal transduction can be activated, such as ion transmembrane transport, active oxide species (AOS) burst, and protein phosphorylation and dephosphorylation [13, 14]. AOS are signal molecules that widely exist in plant cells [13–15]. Hydrogen peroxide (H$_2$O$_2$), one of the AOS, has been considered as the most significant signal molecules [14, 16]. Generally, when plants are under stress, H$_2$O$_2$ is produced rapidly to activate systemic acquired resistance [13, 17, 18] and acts as a signal molecule mediating the biosynthesis of secondary metabolites in plants. For example, H$_2$O$_2$ is the key signal molecule for oligosaccharides to induce the biosynthesis of taxol in T. chinensis cells [19], for the cell wall of Aspergillus niger to elicit Catharanthus roseus cells to synthesize catharanthine [20], for ABA to induce rice seedling leaves to synthesize anthocyanidins [21], and for the cell cultures of Rubia tinctorum to produce anthraquinone [22], and so forth.

Rosmarinic acid (RA) is one of effective compounds of Danshen, the root and rhizome of Salvia miltiorrhiza Bunge, which is used as a traditional Chinese herbal drug which removes blood stasis, stops pain, and activates blood flow and is heart-relieving [23]. RA shows a great intensity for free radical scavenging and antioxidant activity. The
phenylalanine ammonia-lyase (PAL) is the first enzyme for accumulating phenolic acid compounds in S. miltiorrhiza cell cultures [10], and SA could induce the production of rosmarinic acid [24]. The aim of this work is to reveal the effects of SA and H$_2$O$_2$ on the accumulation of RA in S. miltiorrhiza cell cultures. For this purpose, imidazole (IMD, NADPH oxidase inhibitor) is used to inhibit the enzyme activity of NADPH oxidase, and dimethylthiourea (DMTU, H$_2$O$_2$ scavenger) is employed as scavenger of H$_2$O$_2$.

2. Results

2.1. Effects of SA on PAL Activity, H$_2$O$_2$ Production, and RA Accumulation. The PAL activity increased from 20 min after treating with 22.5 mg/L SA and reached the peak at 16 h, when the activity was 5.46 folds of that of control, followed by subsequent decrease (Figure 1(a)). The H$_2$O$_2$ production induced by SA also exhibited continuous increase at the beginning with two peaks, but decreased rapidly after 2-h elicitation. The first peak occurred at 20 min and the second did at 2 h, when 8.51 folds H$_2$O$_2$ production was found in SA-treated cells (Figure 1(b)). In terms of RA accumulation, continuous increase was found till the 2nd day when RA content reached the highest with 2.15 folds and then it decreased gradually (Figure 1(c)).

2.2. Effects of Exogenous H$_2$O$_2$ on the PAL Activation and RA Production. The effects of H$_2$O$_2$ on activation of PAL activity and RA production were investigated, after applying exogenous H$_2$O$_2$ with concentration ranging from 1 to 70 mM. The activity of PAL and RA content were enhanced with the increase of H$_2$O$_2$ concentration ranging from 1 to 10 mM, whereas both decreased if the concentration was more than 10 mM (Figure 2). This result suggests that 10 mM is an appropriate concentration to enhance PAL activity and RA accumulation.

To further estimate the suitable treatment time of H$_2$O$_2$, continuous 6-day treatment was performed to confirm the best time point. Both PAL activity and RA accumulation were increased at early stage with time extension and then decreased at the late stage (Figure 3). The activity of PAL reached the highest peak at 8 h, followed by drastic decrease. The RA content reached the peak at 1 d and decreased drastically after 2 d.

2.3. Influences of CAT on SA-Induced RA Production. CAT is a scavenger of H$_2$O$_2$, which can not pass through cell membrane, and thus the exogenous CAT cannot scavenge H$_2$O$_2$ within cells. Both contents of H$_2$O$_2$ (Figure 4(a)) and RA (Figure 4(b)) were slightly lower than those of control after adding CAT, whereas both contents showed no significant difference between CAT + SA-treated and SA-elicited cells. The application of CAT did not affect the production of endogenous H$_2$O$_2$ and RA accumulation in cells that were subjected to SA elicitation. However, CAT can scavenge the exogenous H$_2$O$_2$, thereby eliminating the production of H$_2$O$_2$ and RA synthesis due to H$_2$O$_2$ regulation. This indicates that the RA biosynthesis is mediated by intracellular H$_2$O$_2$ elicited by SA.

2.4. Influences of DMTU on SA-Induced RA Production. DMTU is a H$_2$O$_2$ quencher that can effectively remove H$_2$O$_2$ within cells. The results showed that H$_2$O$_2$ was released and RA accumulated due to SA elicitation (Figure 1(b)). In order to further explain whether endogenous H$_2$O$_2$ was involved in the activation of PAL and the synthesis of RA, DMTU was employed to quench endogenous H$_2$O$_2$, and under such condition, both contents of H$_2$O$_2$ and RA in cells were measured (Figure 5).

The production of endogenous H$_2$O$_2$ (Figure 5(a)) and the accumulation of RA (Figure 5(b)) within cells were partially inhibited by 100 $\mu$M DMTU, and they were significantly inhibited with the concentration of 500 $\mu$M. If the cells were treated by 500 $\mu$M DMTU + 22.5 mg/L SA or 500 $\mu$M DMTU + 10 mM H$_2$O$_2$, DMTU would significantly inhibit the production of endogenous H$_2$O$_2$ and the accumulation of RA. Application of exogenous H$_2$O$_2$ and/or SA could partially reverse the inhibition of DMTU on RA synthesis. The treatment of 700 $\mu$M DMTU also completely inhibited the production of H$_2$O$_2$ in cells, and the inhibition could not be reversed by application of exogenous SA or H$_2$O$_2$. These results showed DMTU treatment slightly decreased both contents of RA and H$_2$O$_2$, when compared with the H$_2$O$_2$ control. Meanwhile, DMTU + SA treatment would significantly block both contents if compared with those SA-elicited cells. These results indicated that H$_2$O$_2$ produced from SA elicitation is necessary for triggering the biosynthesis of RA.

2.5. Influences of IMD on SA-Induced RA Production. NADPH oxidase is one of the key enzymes for the generation of intracellular H$_2$O$_2$ [25, 26]. IMD is the specific inhibitor of NADPH oxidase on plasma membrane, which can inhibit the production of H$_2$O$_2$ through inactivating NADPH oxidase [16, 17, 25]. For instance, IMD scavenged H$_2$O$_2$ produced from NADPH oxidase elicited by ABA and decreased the synthesis of anthocyanins in rice leaves [21]. In this study, IMD was used to inhibit the activity of NADPH oxidase to examine its influence on the biosynthesis of RA elicited by exogenous H$_2$O$_2$ and/or SA.

When IMD (100 $\mu$M) was used solely, IMD treatment slightly decreased the contents of RA and H$_2$O$_2$ when compared with the control, while IMD + SA and IMD + H$_2$O$_2$ treatments significantly decreased both contents when compared with SA-elicited cells (Figure 6). The results indicated that IMD inhibited the effects of SA elicitation, and the inhibition of IMD to the synthesis of RA in cell cultures depended on H$_2$O$_2$ generated from NADPH oxidase.

3. Discussion

This investigation shows SA can induce the burst of H$_2$O$_2$, and the elicited H$_2$O$_2$ enhances the PAL activity and RA accumulation in S. miltiorrhiza cell cultures. SA signaling
pathways in plant defense network have been widely inves-
tigated during the past two decades [27, 28], but their role in secondary metabolism is rather limited. Zitta et al. [29] reports that 10 μM SA lead to a significant 4-fold increase in H₂O₂ concentrations, which may be attributed to the fact that SA can directly reduce the activity of catalase that decompose of H₂O₂ (Figure 4). As in our study, the content of H₂O₂ in SA-elicited cells was 8.51-fold higher than that of water control (Figure 1), which is consistent with these reports. Although low level (<10 μM) of H₂O₂ is thought to result in the induction of various intracellular signaling pathways [28, 29], application of either exogenous H₂O₂ (10 mM) or endogenous H₂O₂ elicited by SA (22 mg/L) showed its capacity to enhance both PAL activity and RA accumulation
in our experiments. PAL is the first key enzyme in the phenylpropanoid pathway for the biosynthesis of RA [30], which has been reported to be enhanced by SA in the colonization of arbuscular mycorrhizal fungus [28] and in the interaction between tomato plants and Fusarium oxysporum f. sp. lycopersici [31]. H$_2$O$_2$ comes to light as a second messenger involved in SA-elicited pathway. In this paper, both PAL activity and RA accumulation were significantly increased when exogenous 10 mM H$_2$O$_2$ was applied (Figure 2). On the other hand, H$_2$O$_2$ could be elicited by SA even though it was treated by catalase or DMTU (Figures 4 and 5), and the elicited H$_2$O$_2$ also could significantly promote RA accumulation. Our results are consistent with those reports in the fact that H$_2$O$_2$ is involved in many elicitor-induced processes to produce secondary metabolites, for instance, the biosynthesis of taxol [19], catharanthine [20], anthocyanidins [21], and anthraquinone [22]. Increasing evidence proved that plant responses to elicitors, including enzymes activation and the production of secondary metabolites, are not only regulated by signaling pathway, but also a cross-talk process. The mechanism about cross-talk among SA, H$_2$O$_2$, enzyme activity, and synthesis of secondary metabolites has gained some attention recently, but related studies are rare [32]. According to the latest progress in our lab, both nitric oxide (NO) and increase of intracellular Ca$^{2+}$ are also involved in this cross-talk during SA induction.

Taken together, H$_2$O$_2$ production can be elicited by SA and the elicited H$_2$O$_2$ can promote PAL activity and RA accumulation, in which H$_2$O$_2$ plays an important role as a second messenger in signal transduction when SA is applied.

4. Experimental Section

4.1. Cell Culture. The detailed protocols of S. miltiorrhiza cell culture were provided by Dong et al. [10]. The seeds were collected from Shangluo, Shaanxi Province, and then soaked in water for 2–4 h. The wax coat was removed by gauze, followed by washing with water. The seeds were soaked in 70% ethanol for 30 s. After washing by sterile water for 3 times, the seeds were sterilized by 0.1% HgCl$_2$ for 10–15 min. They were sown in the autoclaved MS solid media after washing with sterile water for three times, supplemented with 5.5 g/L agar (Beijing Kangbeisi Sci & Tech Company) and 30 g/L sucrose (Guangzhou Jinhua Chemical Company) to induce the germ free seedlings. The leaves of germ free seedlings were cut into 0.5 cm × 0.5 cm pieces and inoculated on the autoclaved MS solid medium supplemented with 1.0 mg/L NAA (Tianjin Bodi Chemical Company), 1.0 mg/L 6-BA (Beijing Kangbeisi Sci & Tech Company), 1.0 mg/L 2,4-D (Beijing Kangbeisi Sci & Tech Company), 5.5 g/L agar, and 30 g/L sucrose. Calli were induced and cultured at 25 ± 2°C with light intensity of 2000–3000 Lx for 12–16 h per day. After 15-day culture, the calli would be subcultured till two months when their morphological characteristics and growth rates were stable. The stable calli were collected and inoculated in MS liquid media (containing 30 g/L sucrose) with the ratio of callus to culture medium 1:15 (W/V). The suspension cells were cultured in the dark at 25°C with shaking speed of 125 rpm.

4.2. Elicitation and Chemical Treatments. Stock solutions of SA, H$_2$O$_2$, DMTU (H$_2$O$_2$ scavenger, Sigma, USA), CAT (Sigma, USA), and IMD (NADPH scavenger, Sigma, USA) were prepared in distilled water and then sterilized after filtration through 0.22 μm membrane. The resultant solutions with different concentrations were added in the media in accordance with the experimental design. In the control group, only distilled water with the same volume was added to substitute for the chemicals. DMTU, CAT, and IMD were added separately to the cell culture 30 min before SA treatment. All experiments were performed with three replications.

4.3. PAL Activity Assay. PAL activity was measured according to the method of Solecka and Kacperska [33] with some modifications. Fresh cultured calli were placed on filter paper in a Bucher funnel, filtered in vacuum, washed by distilled water, and filtered in vacuum again to remove the facial water. Two grams of calli were homogenized with 5 mL extraction buffer in a mortar. The homogenate was filtered through four-layer cheesecloth and centrifuged at 10000 rpm for 15 min at 4°C to get supernatant that would be used as a crude enzyme. The reaction mixture (3 mL) included 0.5 mL crude enzyme, 16 mM L-phenylalanine, 50 mM Tris-HCl buffer (pH 8.9), and 3.6 mM NaCl. The mixture was incubated at 37°C for 60 min and the reaction was stopped by 500 μL 6 M HCl. The resultant mixture was then centrifuged (12,000 × g, 10 min). The absorbance was measured at 290 nm before and after incubation. The enzyme activity (U) was calculated by the following equation:

\[
PAL(U \cdot g^{-1}FW \cdot h^{-1}) = \frac{A_{290} \times v_p \times v}{0.01 \times V_s \times FW \times t},
\]

where $V_s$ represents the total volume of enzyme solution (mL); FW is the fresh weight of calli; $V_s$ is the volume of
4.4. Determination of Hydrogen Peroxide. Hydrogen peroxide was determined by the method of Li et al. [34]. The calli (0.2–0.3 g) were homogenized with 5 mL acetone precooled under 4°C and then ground to homogenate on the ice. The mixture was centrifuged at 12,000 rpm for 10 min at 4°C. The supernatant (2 mL) was mixed quickly with 0.5 mL 5% titanium sulfate, and ammonia solution (2 mL) was added and homogenized. The resultant mixtures were then centrifuged again; the supernatant was discarded. The precipitate (the titanium-hydro peroxide complex) was dissolved in 5 mL 2 M sulfuric acid, and the supernatant absorbance was measured at 415 nm, and the content of hydrogen peroxide was calculated.

4.5. RA Extraction and HPLC Analysis. The S. miltiorrhiza cells were collected from cell cultures by centrifugation at 1200 rpm, and then dried at 47.5°C in an oven till constant weight. The dried cells (0.05 g) were put into a test tube with a stopper, and the extraction was conducted with aqueous methanol (70: 30, methanol: water) for 45 min in an ultrasonic bath. The extract was filtered through a 0.22 μm membrane and the filtrate was obtained for detection. The content of RA was quantified by HPLC (Shimadzu, model SCL-10AVPTM equipped with UV/Vis absorbance detector, 150 mm × 4.6 mm shim-pack column,
and LC-ATVP pump). The mobile phase was acetonitrile:water:phosphate (25:75:0.1, v/v/v). The flow rate was 1 mL/min and the injection amount was 10 μL. The detection wavelength was 285 nm and the column temperature was 25°C.

5. Conclusions

SA is an effective elicitor inducing RA accumulation in S. milioti rhiza cell cultures, which can act independently or synergistically with H2O2. The intracellular H2O2 acts as a signal molecule to participate in RA accumulation in response to SA elicitation.
