In this paper, a three-dimensional polar code (3D-PC) scheme is proposed to improve the error floor performance of parallel concatenated systematic polar code (PCSPC). The proposed 3D-PC is constructed by serially concatenating the PCSPC with a rate-1 third dimension, where only a fraction $\lambda$ of parity bits of PCSPC are extracted to participate in the subsequent encoding. It takes full advantage of the characteristics of parallel concatenation and serial concatenation. In addition, the convergence behavior of 3D-PC is analyzed by the extrinsic information transfer (EXIT) chart. The convergence loss between PCSPC ($\lambda = 0$) and different $\lambda$ provides the reference for choosing the value of $\lambda$ for 3D-PC. Finally, the simulation results confirm that the proposed 3D-PC scheme lowers the error floor.

1. Introduction

The novel concept of parallel concatenated systematic polar code (PCSPC) was first put forward in [1]. PCSPC scheme consists of two systematic polar codes (SPCs) [2]. It has performance advantage with respect to original SPC. In [3], the extrinsic information transfer (EXIT) charts of different length SPC have been given. As a promotion of the above EXIT chart results, the convergence behavior of PCSPC can be analyzed. It can be observed that SPC with larger code length leads to narrower opening. Therefore, it is difficult for PCSPC with large code length SPCs to converge at low error rate. The motivation of our work is to solve this problem.

As we know, there is error floor for turbo code (TC) at block error rate (BLER) around $10^{-5}$ [4]. In order to improve the performance of TC in the error floor region, three-dimensional turbo code (3D-TC) has been studied in [5–7]. 3D-TC scheme was proposed by serially concatenating a rate-1 cyclic recursive systematic convolutional (CRSC) code to conventional TC. It is important to note that only a fraction $\lambda$ of parity bits from TC are extracted to participate in the encoding again. Compared with conventional TC, 3D-TC scheme has larger minimum distance. Therefore, 3D-TC improves the error floor performance greatly. In addition, the influence of $\lambda$ of 3D-TC on convergence threshold and minimum distance has been researched in [6, 7].

It is known from the literature that serial concatenated code has larger minimum distance with respect to parallel concatenated code; however, its convergence threshold is worse than that of parallel concatenation [8]. Meanwhile, inspired by the idea in [7], 3D polar code (3D-PC) scheme is proposed to improve the error floor performance of PCSPC in this paper. It makes full use of the features of parallel concatenation and serial concatenation. 3D-PC is constituted by adding a rate-1 CRSC code to PCSPC. And only a fraction $\lambda$ of parity bits of PCSPC are sent to the third encoder. Moreover, the convergence behavior of 3D-PC is analyzed by EXIT chart method [9]. It can be utilized to guide the choice of $\lambda$ which is an important parameter that affects the performance of 3D-PC. Simulation results corroborate the effectiveness of 3D-PC scheme to improve the low error rate performance.

The paper is organized as follows. Section 2 reviews systematic polar code and EXIT chart. 3D-PC scheme is proposed in Section 3. In Section 4, convergence analysis of 3D-PC is presented. The simulation results are shown in Section 5. Section 6 concludes this paper.
2. Preliminaries

2.1. Systematic Polar Code. Polar code is a capacity-achieving channel code which was proposed by Arikan in [10]. Given code length \( N \) and code rate \( R = K/N \), the reliabilities of \( N \) subchannels can be obtained by Gaussian approximation method [11] or other construction algorithms. Then the \( K \) subchannels with high reliability are used to transmit information bits, and other \( N - K \) subchannels are utilized to deliver frozen bits. Let set \( \mathcal{A} \subset \{1, \ldots, N\} \) denote the indexes of those \( K \) high reliability subchannels. Supposing that the input sequence \( v = (v_1, \ldots, v_N) \) is given, the codeword \( x \) of polar code can be obtained by

\[
x = vG_N = v(B_N F_2^{\text{per}}),
\]

where \( G_N \) is the generator matrix, \( B_N \) denotes the bit-reversal permutation matrix, \( \text{per}n \) denotes the \( n \)-th Kronecker product, and \( F_2 = [1 \ 1] \).

Since the input source sequence \( v \) can be decomposed into two parts \( v_{af} \) and \( v_{sf} \), the codeword \( x \) in (1) can be written as

\[
x = vG_N = v_{af}G_{af} + v_{sf}G_{sf},
\]

where \( v_{af} \subset v \) is the information bits, \( \mathcal{A} = \{1, \ldots, N\} \), \( \mathcal{A} \) denotes the complement of \( \mathcal{A} \), and \( G_{af} \) consists of the rows of \( G_N \) with indices in \( \mathcal{A} \).

Systematic polar code is constructed based on polar code [2]. Assume that \( K \)-elements set \( \mathcal{B} \) denotes the indexes of system bits; then \( x_{af} \) denotes system bits and \( x_{sf} \) is the check bits. Equation (2) can be rewritten as

\[
x_{af} = v_{af}G_{af,b} + v_{sf}G_{sf,b}, \quad x_{sf} = v_{af}G_{af,c} + v_{sf}G_{sf,c},
\]

where \( G_{af,b} \) denotes the submatrix of \( G_N \) with row indexes in \( \mathcal{A} \) and column indexes belonging to \( \mathcal{B} \).

As to SPC, the systematic bits \( x_{af} \) are known and \( v_{sf} \) are also known and set to zero; thus \( v_{sf} \) can be calculated according to (3):

\[
v_{af} = (x_{af} - v_{af}G_{af,b})(G_{af,c})^{-1} = x_{af}(G_{af,c})^{-1}. \quad (5)
\]

Further, the check bits \( x_{sf} \) can be computed by (4):

\[
x_{sf} = x_{af} \left[ (G_{af,b})^{-1} G_{af,c} \right]. \quad (6)
\]

Here, the codeword \( x \) of SPC is achieved.

2.2. EXIT Chart. EXIT chart [9] is an efficient convergence analysis tool for the iterative decoding structure. It tracks the average mutual information of constituent decoders.

We use \( X \) and \( A \) to denote the transmitted bits and the corresponding a priori information, respectively. And \( A \) is modeled as an independent Gaussian random variable with the following expression:

\[
A = \mu_A x + n_A
\]

with

\[
\mu_A = \frac{\sigma_A^2}{2}, \quad \sigma_A = \frac{\sigma^2}{2}
\]

where \( n_A \) is a Gaussian random variable with mean zero and variance \( \sigma_A^2 \). Under the above assumption, the mutual information between transmitted bits \( X \) and a priori information \( A \) can be written as

\[
I_A = I(X; A) = 1 - \frac{1}{2} \int_{-\infty}^{+\infty} \frac{1}{\sqrt{2\pi}\sigma_A} e^{-\left(\frac{x^2}{2}\right)} \log_2 \left( 1 + e^{-x} \right) dx.
\]

Assume that extrinsic information is denoted by \( E \). The mutual information between \( X \) and \( E \) is calculated as

\[
I_E = I(X; E) = \frac{1}{2} \sum_{x=-1}^{1-\lambda} \int_{-\infty}^{+\infty} p_E(\xi | X = x) \log_2 \frac{2 \cdot p_E(\xi | X = x)}{p_E(\xi | X = -1) + p_E(\xi | X = +1)} d\xi,
\]

where \( p_E(\xi | X = x) \) is the probability distribution function given condition \( X = x \). It can be obtained by Monte Carlo simulation.

3. Proposed 3D Polar Code Scheme

3.1. Encoding Structure. In short, 3D-PC scheme can be regarded as a concatenation of the inner code and outer code, PCSPC. The encoding structure of 3D-PC is illustrated in Figure 1. First of all, the input information sequence \( u \) with length \( K \) is encoded by parallel concatenated systematic polar encoder. The component encoders of PCSPC are written as \( C_a \) and \( C_b \), respectively. Both of them are systematic polar encoders. We use \( x_a \) and \( x_b \) to denote the parity bits sequence of \( C_a \) and \( C_b \), respectively. Further, the codeword \( x_{PC} \) can be obtained by taking the bits from \( x_a \) and \( x_b \) alternatively. The fraction \( \lambda \) of \( x_{PC} \) is interleaved by the interleaver \( \Pi_c \) and sent to the postencoder \( C_c \) for encoding, where \( \lambda \) is named as permeability rate. And codeword \( x_c \) is output by the postencoder \( C_c \). The parity bits chosen for encoding follow a certain puncturing pattern \( p \) with length \( 2/\lambda \). The fraction \( 1 - \lambda \) of \( x_{PC} \) is passed to the channel straightly, denoted by \( x_{ch} \). The patterns \( \bar{p} \) and \( p \) are complementary. Furthermore, the last codeword \( x \) of 3D-PC with code length \( N_T \) is obtained by combining the input sequence \( u \), the parity sequence \( x_{ch} \), and the parity sequence \( x_c \). Here the code rate of 3D-PC is calculated by \( R = K/N_T = 1/3 \). In order to achieve higher code rate, it is need to puncture some parity bits from \( x_{ch} \) or \( x_c \). Since \( x_c \) contains more information, \( x_{ch} \) is first taken into consideration.

For complexity and performance reasons, the selected \( C_c \) encoder should meet some requirements: its decoder is as simple as possible, its decoder inputs soft information and outputs soft information, and its decoder should not
monitor too much error [5]. As a result, a rate-1 cyclic recursive systematic convolutional encoder with generator polynomial \( g(D) = 1/(1 + D^2) \) is selected as the encoder \( C_c \) [6].

In literature [5, 6], the interleavers \( \Pi \) and \( \Pi_c \) have been well designed to increase the minimum distance. Because the design of interleaver has a great influence on the performance of TC. While the effect of interleaver on polar code is not so obvious, random interleaver is considered in this 3D polar encoding structure for convenience.

In this paper, regular puncturing pattern is applied to \( p \). If \( p \) is adopted to \( x_{PC} \) with length \( N_c \), there are altogether \( N_c \lambda \) ones in the period \( N_c \). The bits of \( x_{PC} \) corresponding to the positions of \( N_c \lambda \) ones are not punctured. For example, assume that \( \lambda = 1/4 \) and \( p = [11000000] \); then every fourth bit of \( x_a \) and \( x_b \) is extracted and sent to \( C_c \) for encoding again. According to the relationship between \( p \) and \( \bar{p} \), it is easy to obtain \( \bar{p} = [00111111] \). If we apply \( \bar{p} \) to \( x_{PC} \), then the bits which are reserved are sent to the channel.

3.2. Decoding Structure. In general, a concatenated code can be decoded by the iterative decoding structure. The decoding diagram of 3D-PC is shown in Figure 2. The sequence \( y \) is received from channel \( W \) and is demultiplexed into three parts, \( y_w, y_{ch}, \) and \( y_e \). The corresponding channel logarithm likelihood ratios (LLRs) are denoted by \( \Psi_w, \Psi_{ch}, \) and \( \Psi_e \). Later they participate in the subsequent decoding. The decoders \( C_{a,c}^{-1}, C_{b,c}^{-1}, \) and \( C_{c,c}^{-1} \) are corresponding to encoders \( C_a, C_b, \) and \( C_c \), respectively.

First, \( \Psi_e \) from channel and \( \Gamma_e \) from \( C_{a,c}^{-1} \) and \( C_{b,c}^{-1} \) are fed to \( C_{c,c}^{-1} \) for decoding. Then the extrinsic information \( \Lambda_e \) is deinterleaved, combined with \( \Psi_{ch} \) and demultiplexed into two parts, \( \Psi_a \) and \( \Psi_b \). The obtained \( \Psi_a \) and \( \Psi_b \) are regarded as channel LLRs of parity bits and assist \( C_{a,c}^{-1} \) and \( C_{b,c}^{-1} \) in decoding, respectively. For outer decoder, the extrinsic information related to \( u \) is exchanged between \( C_{a,c}^{-1} \) and \( C_{b,c}^{-1} \) because both the input information of \( C_a \) and that of \( C_b \) are from \( u \). Additionally, the extrinsic information, \( \Xi_a \) and \( \Xi_b \), of parity bits which is output by \( C_{a,c}^{-1} \) and \( C_{b,c}^{-1} \) goes through the following operations: multiplex, puncture, and interleave. Then extrinsic LLR information \( \Gamma_e \) is obtained and delivered to \( C_{c,c}^{-1} \) as a priori information at next iteration. The extrinsic LLR information of part parity bits \( x_p \) is exchanged between inner decoder \( C_{c,c}^{-1} \) and outer decoder as framed in Figure 2. The exchange procedure is terminated when the given out-loop iteration number is reached and the decision is made by the LLR information of \( C_b^{-1} \).

Since it is needed to exchange extrinsic information between \( C_{a,c}^{-1} \) and \( C_{b,c}^{-1} \), the decoder adopted should meet the soft-in-soft-out (SISO) requirement. As to the decoding of SPC, there are two SISO decoding algorithms, belief propagation (BP) decoding [12] and soft cancellation (SCAN) decoding [13]. Therefore, BP decoder and SCAN decoder can be considered for the decoders \( C_{a,c}^{-1} \) and \( C_{b,c}^{-1} \).

As to the decoding of tail-biting convolutional code, the optimal algorithm is maximum a posteriori probability (MAP) decoding algorithm, but its complexity is very high. Two suboptimal MAP decoding algorithms have been proposed for tail-biting convolutional code. tail-biting BCJR (TB-BCJR), and A3 [14]. Afterwards, a less complexity MAP algorithm has been presented to decode tail-biting convolutional code [15]. Therefore, the TB-BCJR, A3 algorithms and the low complexity MAP algorithm can be chosen as the candidate schemes for \( C_{c,c}^{-1} \) decoder.

4. Convergence Behavior Analysis

In this part, EXIT chart is utilized to analyze the convergence threshold of 3D-PC. In Figure 3, the simplified decoding structure for the calculation of EXIT chart is given. In Figure 3, \( I_{A,inner} \) denotes the average mutual information between \( A(u) \) and \( u \), \( I_{E,inner} \) denotes the average mutual information between \( E(u) \) and \( u \), \( I_{A,outer} \) denotes the average mutual information between \( A(x_p) \) and \( x_p \), and \( I_{E,outer} \) denotes the average mutual information between \( E(x_p) \) and \( x_p \). The detailed calculation processes of EXIT chart curve are presented as follows:

1. Given signal to noise ratio (SNR), \( u \), and \( 0 \leq I_{A,inner} \leq 1 \); then the a priori information \( A(u) \) can be obtained by the assumed model [9] and is sent for the inner decoder \( C_{c,c}^{-1} \).
2. Monte Carlo simulation based on \( C_{c,c}^{-1} \) is performed to get the distributions of \( p_E \) of (10).
3. Then \( I_{E,inner} \) is calculated by substituting \( p_E \) into (10).
4. Traverse \( I_{A,inner} \) at a certain step size in a certain internal \([0, 1]\) and calculate the corresponding \( I_{E,inner} \). Then the curve which depicts the relation between \( I_{E,inner} \) and \( I_{A,inner} \) is obtained.

<td>3.16 dB</td>
<td>2.60 dB</td>
</tr>
</tbody>
</table>

Figure 4: EXIT chart of $\lambda = 1/4, R = 1/3$, 3D-PC, SNR = 3.41 and of $\lambda = 1/2, R = 1/3$, 3D-PC, SNR = 4.8.

Likewise, $I_{E,outer}$ can be got by the above processes. The differences are that the decoder for Monte Carlo simulation is outer decoder other than $C_c^{-1}$, $I_{A,outer}$ is given, and the transmitted bits are $x_p$ instead of $u_c$.

Figure 4 gives the EXIT chart of 3D-PC with two configurations, $\{\lambda = 1/4, R = 1/3, \text{SNR} = 3.41\}$ and $\{\lambda = 1/2, R = 1/3, \text{SNR} = 4.8\}$. The EXIT chart curves of the outer code and inner code are denoted by solid curves and dash curves, respectively. From Figure 4, it can be seen that there is an opening between the EXIT chart curves of inner code and outer code for both configurations. Since there is no disjoint for each pair of EXIT chart curves, the decoding of 3D-PC can reach convergence. In general, the EXIT chart curves can be depicted with the variety of SNR. The convergence threshold is the SNR at which the tunnel between EXIT chart curves pairs is very narrow. As to 3D-PC with $\lambda = 1/4$ and $R = 1/3$, the convergence threshold is 3.4 dB. Table 1 lists the convergence thresholds of 3D-PC under different $\lambda$. The simulation frames for Monte Carlo simulation are $1.0 \times 10^5$.

From Table 1, it can be observed that the convergence threshold increases with the increase of $\lambda$. Compared with the best convergence threshold when $\lambda = 0$, the convergence loss under $\lambda = 1/8$ and $\lambda = 1/4$ is relatively small. Therefore, those two $\lambda$ configurations are set to 3D-PC.

5. Simulation Results

In Figure 5, the BLER performance of 3D-PC is given. The underlying channel is additive white Gaussian noise (AWGN)
As a comparison scheme, the performance of PCSPC is also given in Figure 5. The constituent codes are SPCs with code rate 1/2 and code length 8192. Under this configuration, the total code rate of 3D-PC is R = 1/3. The interleavers Π and Π̄, used for simulation are random interleavers. The internal iteration number of outer decoder is 1 and the iteration number between the inner decoder and the outer decoder is equal to 6. In addition, SCAN decoding algorithm is utilized for the decoding of SPC and the CRSC code is decoded by low complexity MAP decoding [15]. Different permeability rates λ are set to 3D-PC scheme, such as 1/4 and 1/8.
